ABSTRACT

In multi-class text classification, the performance (effectiveness) of a classifier is usually measured by micro-averaged and macro-averaged F1 scores. However, the scores themselves do not tell us how reliable they are in terms of forecasting the classifier’s future performance on unseen data. In this paper, we propose a novel approach to explicitly modelling the uncertainty of average F1 scores through Bayesian reasoning.

General Terms

Experimentation, Measurement, Performance

Keywords

Text Classification; Performance Evaluation; Bayesian Inference

1. INTRODUCTION

Automatic text classification [7] is a fundamental technique in information retrieval (IR) [4]. It has many important applications, including topic categorisation, spam filtering, sentiment analysis, message routing, language identification, genre detection, authorship attribution, and so on. In fact, most modern IR systems for search, recommendation, or advertising contain multiple components that use some form of text classification.

The most widely used performance measure for text classification is the F1 score [8] which is defined as the harmonic mean of precision and recall. It is known to be more informative and more useful than classification accuracy etc. due to the prevalent phenomenon of class imbalance in text classification. When multiple classes exist in the document collection (such as Reuters-21578 with its 118 classes), we often want to compute a single aggregate measure that combines the F1 scores for individual classes. There are two methods to do this: micro-averaging and macro-averaging [4]. The former pools per-document decisions across classes, and then computes the overall F1 score on the pooled contingency table. The latter just computes a simple average of the F1 scores over classes. The differences between these two averaging methods can be large: micro-averaging gives equal weight to each per-document classification decision and therefore is dominated by large classes, whereas macro-averaging gives equal weight to each class. It is nowadays a common practice for IR researchers to evaluate a multi-class text classifier using both the micro-averaged F1 score (denoted as miF1) and the macro-averaged F1 score (denoted as maF1), since their introduction by Yang and Liu’s seminal SIGIR-1999 paper [9].

However, the average F1 scores themselves only reflect a text classifier’s performance on the given test data. How can we be sure that it will work well on unseen data? Given any finite amount of test results, we can never be guaranteed that one classifier’s performance will definitely achieve a certain acceptable level (say 0.80) in practice. For example, suppose that a classifier got miF1 0.81 on 100 test documents. Due to the small number of test documents, we probably do not have much confidence in pronouncing that its future performance will be above 0.80. If instead the classifier got maF1 0.81 on 100,000 test documents, we can be more confident than in the previous case. Nevertheless, there will always be some degree of uncertainty. The central question here is how to assess the uncertainty of a classifier’s performance as measured by miF1 and maF1, given a set of test results.

In this paper, we address this problem by appealing to Bayesian reasoning [3], and demonstrate that our approach provides rich information about a multi-class text classifiers’ performance.

2. OUR APPROACH

2.1 Model

Let us consider a multi-class classifier which has been tested on a collection of N labelled test documents, D. Here we focus on the setting of multi-class single-label (aka “one-of”) classification where one document belongs to one and only one class [4,7]. For each document \(x_i\) \((i = 1, \ldots, N)\),
we have its true class label $y_j$ as well as its predicted class label $\hat{y}_j$. Given that there are $M$ different classes, the classification results could be fully summarised into an $M \times M$ confusion matrix $C$ where the element $c_{jk}$ at the $j$-th row and the $k$-th column represents the number of documents with true class label $j$ but predicted class label $k$, as shown in Figure 1.

The performance measures $miF_1$ and $maF_1$ can be calculated straightforwardly based on such a confusion matrix. However, as we have explained earlier, we are not satisfied with knowing only a single score value of the performance measure, but instead would like to treat the performance measure (either $miF_1$ or $maF_1$) as a random variable $\psi$ and estimate its uncertainty by examining its posterior probability distribution.

The test documents can be considered as “independent trials”, i.e., their true class labels $y_j$ are independent and identically distributed (i.i.d.). For each test document, we use $\mu = (\mu_1, \ldots, \mu_M)$ to represent the probabilities that it truly belongs to each class: $\mu_j = Pr[y_j = j] \ (j = 1, \ldots, M), \sum_{i=1}^M \mu_j = 1$. This means that the class sizes $n = (n_1, \ldots, n_M)$ would follow a Multinomial distribution with parameter $\mu$ and $\mu: n \sim \text{Mult}(N, \mu)$, i.e.,

$$Pr[n|N, \mu] = \frac{N!}{n_1! \cdots n_M!} \prod_{j=1}^M \mu_j^{n_j} = \frac{\Gamma(\sum_{j=1}^M n_j + 1)}{\prod_{j=1}^M \Gamma(n_j + 1)} \prod_{j=1}^M \mu_j^{n_j}.$$ 

It would then be convenient to use the Dirichlet distribution (which is conjugate to the Multinomial distribution) as the prior distribution of parameter $\mu$. More specifically, $\mu \sim \text{Dir}(\beta)$, i.e.,

$$Pr[\mu] = \frac{\Gamma(\sum_{j=1}^M \beta_j)}{\prod_{j=1}^M \Gamma(\beta_j)} \prod_{j=1}^M \mu_j^{\beta_j - 1},$$

where the hyper-parameter $\beta = (\beta_1, \ldots, \beta_M)$ encodes our prior belief about each class’s proportion in the test document collection. If we do not have any prior knowledge, we can simply set $\beta = (1, \ldots, 1)$ that yields a uniform distribution, as we did in our experiments.

Furthermore, let $c_j = (c_{j1}, \ldots, c_{jM})$ denote the $j$-th row of the confusion matrix. In other words, shows how those documents belonging to class $j$ are classified. For each test document from that class $j$, we use $\theta_j = (\theta_{j1}, \ldots, \theta_{jM})$ to represent the probabilities that it is classified into different classes: $\theta_{jk} = Pr[\hat{y}_j = k | y_j = j] \ (k = 1, \ldots, M), \sum_{k=1}^M \theta_{jk} = 1$. This means that for each class $j$, the corresponding vector $c_j$ would follow a Multinomial distribution with parameter $n_j$ and $\theta_j$: $c_j \sim \text{Mult}(n_j, \theta_j)$, i.e.,

$$Pr[c_j|n_j, \theta_j] = \frac{n_j!}{c_{j1}! \cdots c_{jM}!} \prod_{k=1}^M \theta_{jk}^{c_{jk}} = \frac{\Gamma(\sum_{k=1}^M c_{jk} + 1)}{\prod_{k=1}^M \Gamma(c_{jk} + 1)} \prod_{k=1}^M \theta_{jk}^{c_{jk}}.$$ 

It would then be convenient to use the Dirichlet distribution (which is conjugate to the Multinomial distribution) as the prior distribution of parameter $\theta_j$. More specifically, $\theta_j \sim \text{Dir}(\alpha_j)$, i.e.,

$$Pr[\theta_j] = \frac{\Gamma(\sum_{k=1}^M \alpha_jk)}{\prod_{k=1}^M \Gamma(\alpha_jk)} \prod_{k=1}^M \theta_{jk}^{\alpha_jk - 1},$$

where the hyper-parameter $\alpha_j = (\alpha_{j1}, \ldots, \alpha_{jM})$ encodes our prior belief about a classifier’s prediction accuracy for class $j$. If we do not have any prior knowledge, we can simply set for each class $\alpha_j = (1, \ldots, 1)$ that yields a uniform distribution, as we did in our experiments.

Once the parameters $\mu$ and $\theta_j \ (j = 1, \ldots, M)$ have been estimated, it will be easy to calculate, for each class, the contingency table of “expected” prediction results: true positive ($tp$), false positive ($fp$), true negative ($tn$), and false negative ($fn$). For example, the anticipated number of true positive predictions, for class $j$, should be the number of test documents belonging to that class $N\mu_j$ times the rate of being predicted by the classifier into that class as well $\theta_{jj}$. The equations to calculate the contingency table for each class $j$ are listed as follows.

$$tp_j = N\mu_j \theta_{jj}, \quad fp_j = \sum_{v \neq j} N\mu_v \theta_{uj}, \quad tn_j = \sum_{j \neq j \neq v} N\mu_v \theta_{uv}, \quad fn_j = \sum_{v \neq j} N\mu_v \theta_{vj}.$$ 

In micro-averaging, we pool the per-document predictions across classes, and then use the pooled contingency table to compute the micro-averaged precision $P$, micro-averaged recall $R$, and finally their harmonic mean $miF_1$ as follows.

$$P = \frac{\sum_{j=1}^M (tp_j)}{\sum_{j=1}^M (tp_j + fp_j)} = \sum_{j=1}^M \mu_j \theta_{jj}, \quad R = \frac{\sum_{j=1}^M (tp_j)}{\sum_{j=1}^M (tp_j + fn_j)} = \sum_{j=1}^M \mu_j \theta_{jj}, \quad miF_1 = \frac{2PR}{P + R} = \sum_{j=1}^M \mu_j \theta_{jj},$$

It is a well-known fact that in multi-class single-label (aka “one-of”) classification, $miF_1 = P = R$ which is actually identical to the overall accuracy of classification [4].

In macro-averaging, we use the contingency table of each individual class $j$ to compute that particular class’s precision $P_j$ as well as recall $R_j$, and finally compute a simple average of the $F_1$ scores over classes to get $maF_1$ as follows.

$$P_j = \frac{tp_j}{tp_j + fp_j} = \frac{\mu_j \theta_{jj}}{\sum_{u=1}^M \mu_u \theta_{uj}}, \quad R_j = \frac{tp_j}{tp_j + fn_j} = \theta_{jj}.$$
The program is written in Python utilising Markov Chain Monte Carlo (MCMC) techniques. The default configuration is to generate 50,000 samples, with no “burn-in”, “lag”, or “multiple-chains”. The program is written in Python utilising the module PyMC3\(^1\) for MCMC based Bayesian model fitting. The source code will be made open to the research community on the first author’s homepage.

**Figure 2:** The probabilistic graphical model for estimating the uncertainty of average \(F_1\) scores.

\[
maF_1 = \left( \sum_{j=1}^{M} \frac{2P_j R_j}{P_j + R_j} \right) / M
\]

In the above calculation of \(miF_1\) and \(maF_1\), \(N\) has been cancelled out so it does not appear in the final formulae. Therefore the deterministic variable \(\psi\) for the performance measure of interest (either \(miF_1\) or \(maF_1\)) is a function that depends on \(\mu\) and \(\theta_1, \ldots, \theta_M\) only:

\[
\psi = f(\mu, \theta_1, \ldots, \theta_M).
\]

The above model describes the generative mechanism of a multi-class classifier’s test results (i.e., confusion matrix). It is summarised as follows, and also depicted in Figure 2 as a probabilistic graphical model (PGM) [2] using common notations.

\[
\begin{align*}
\mu & \sim \text{Dir}(\beta) \\
n & \sim \text{Mult}(N, \mu) \\
\theta_j & \sim \text{Dir}(\alpha_j) \quad \text{for } j = 1, \ldots, M \\
c_j & \sim \text{Mult}(n_j, \theta_j) \quad \text{for } j = 1, \ldots, M \\
\psi & = f(\mu, \theta_1, \ldots, \theta_M)
\end{align*}
\]

Our model can be considered as a generalisation of the two-class \(F_1\) score model proposed by Goutte and Gaussier [1] to multiple classes. More importantly, it opens up many possibilities for adaptation or extension.

**2.2 Implementation**

The purpose of building the above model for classification results is to assess the Bayesian posterior probability of \(\psi\) that represents either \(miF_1\) or \(maF_1\). An approximate estimation of \(\psi\) can be obtained by sampling from its posterior probability distribution via Markov Chain Monte Carlo (MCMC) [3] techniques.

We have implemented our model with an MCMC method *Metropolis-Hastings sampling* [3]. The default configuration is to generate 50,000 samples, with no “burn-in”, “lag”, or “multiple-chains”. The program is written in Python utilising the module PyMC3\(^1\) for MCMC based Bayesian model fitting. The source code will be made open to the research community on the first author’s homepage.

**3. EXPERIMENTS**

In order to demonstrate the usage of our model for estimating the uncertainty of average \(F_1\) scores, we have conducted experiments on the confusion matrix given by the test results from a multi-class classifier on a real-world text dataset. The confusion matrix provides all the data that our model requires. It is shown in Figure 3 to ensure the reproducibility of experiments.

Our proposed Bayesian estimation approach offers rich information about the given classifier’s average \(F_1\) scores, as shown in Table 1. In addition to the original performance score (\(miF_1\) or \(maF_1\)), we have shown its posterior mean, standard deviation (std), Monte Carlo error (MC error), the percentage lower or greater than the reference performance score 0.8 (LG pct), and the 95% Highest Density Interval (HDI). In particular, the 95% HDI is a useful summary of where the bulk of the most credible values of \(\psi\) falls: by definition, every value inside the HDI has higher probability density than any value outside the HDI, and the total mass of points inside the 95% HDI is 95% of the distribution [3].

The Bayesian estimations of \(miF_1\) and \(maF_1\) are visualised in Figure 4 and 5 respectively. The left component in each figure plots the posterior probability distribution of the performance measure variable \(\psi\), while the right component plots the corresponding MCMC trace which proves the convergence of sampling.

**4. CONCLUSIONS**

The main contribution of this paper is a Bayesian estimation approach to assessing the uncertainty of average \(F_1\) scores in the context of multi-class text classification. Obviously the more general \(F_1\) measure (\(\beta \geq 0\)) \([4, 8]\) can be dealt with in the same way.

Our model for estimating the uncertainty of average \(F_1\) scores has been described in the multi-class single-label (aka “one-of”) classification setting, but it is readily extensible to the multi-class multi-label (aka “any-of”) classification setting \([4, 7]\). In that case, the Dirichlet/Multinomial distributions should simply be replaced by multiple Beta/Binomial distributions each of which corresponds to one specific target class, because a multi-class multi-label classifier is nothing more than a composition of independent binary classifiers.

By modelling the full posterior probability distribution of \(miF_1\) or \(maF_1\), we are able to make meaningful *interval estimation* (e.g., the 95% HDI) instead of simplistic point

Estimation of a text classifier’s future performance on unseen data. The rich information provided by our model will allow us to make comprehensive performance comparisons between text classifiers, by taking the uncertainty of average $F_1$ scores into account. It would be interesting to conduct more extensive experiments to verify whether the proposed Bayesian approach has advantages over traditional hypothesis testing [6,9].
