## **Abstract**

Using data from the United Kingdom, this study explores the institutional and environmental factors that influence universities' efficiency in knowledge transfer. While studies of universities' knowledge transfer performance have so far focused on patent commercialisation and research contracting with industry, it is increasingly acknowledged that universities engage in a broader range of knowledge transfer activities, including consulting, public engagement and provision of knowledge-intensive services. When these are taken into account, less research-intensive universities, and those with a greater share of staff in the arts and humanities, improve their relative efficiency. More specialised, older and larger institutions are more efficient performers, while research intensity is no longer a strong predictor of efficiency.

**Key words:** university performance, knowledge transfer, data envelopment analysis, efficiency, HEBCI survey

**JEL codes:** O32 - Management of Technological Innovation and R&D; D24 - Production; Cost; Capital; Capital, Total Factor, and Multifactor Productivity; Capacity; C34 - Truncated and Censored Models; Switching Regression Models

## **1. Introduction**

Universities are increasingly encouraged to transfer knowledge to stakeholders in business, government and society more generally (Grady and Pratt, 2000; Vorley and Lawton Smith, 2007; Nelles and Vorley, 2010) in order to facilitate spillovers of knowledge, and thus more effectively contribute to economic growth. Engagement in knowledge transfer has been institutionalised as a third mission for universities (Lockett, Wright and Wild 2014; Pinheiro, Langa and Pausits 2015), as important as their longstanding commitment to teaching and research (Etzkowitz, 2002; Lawton Smith 2007). Institutionalisation has largely been driven by policy incentives (Sánchez-Barrioluengo 2014; Pinheiro, Langa and Pausits 2015). Since the late 1990s, policymakers in many countries have encouraged universities to commercialise research results through patents and spinoff companies (Mowery and Sampat 2005; Geuna and Rossi 2011), and to collaborate with industry (Bozeman 2000; Perkmann, Neely and Walsh 2011), through measures such as the provision of knowledge transfer support infrastructures (as in Denmark, Norway and Sweden; Bourelos, Magnusson and McKelvey, 2012), the benchmarking of universities' knowledge transfer performance through surveys (as in the United States, Canada and Australia; Jensen et al. 2009; Association of University Technology Managers, 2011), and the allocation of funds based on universities' knowledge transfer performance (as in the United Kingdom (UK); Rossi and Rosli, 2015). Consequently, clearer understanding of the factors that drive good knowledge transfer performance is important both to university managers, who can appropriately adjust institutional policies, practices and structures (Berbegal Mirabent and Solé Parellada, 2012; Curi, Daraio and Llerena, 2012), and to policymakers, who can devise ways to encourage universities'

performance, for example through the introduction of suitable incentive systems (Ranga and Etzkowitz, 2013).

Knowledge transfer performance has many dimensions. While the current policy debate mainly concerns the development of metrics to precisely and comprehensively capture knowledge transfer outputs (Guerrero, Cunningham and Urbano, 2015), another important performance dimension is what management research calls ‘efficiency’ (Drucker, 1977, Griffin, 1987 and Anthony, Dearden and Bedford, 1989): ‘how well’ universities use their resources to produce outputs, rather than ‘how much’ of these outputs they produce. Universities largely finance their knowledge transfer activities with the same resources used to support their research and teaching missions<sup>1</sup>: although a substantial literature has investigated efficiency in research and teaching, there is still limited understanding of how to measure efficiency in knowledge transfer and of what factors underpin universities’ efficient performance in this domain.

Moreover, most studies of knowledge transfer efficiency focus on the embedding of university research findings into intellectual property (IP) protection instruments such as patents, or on their commercialisation through licenses (Grady and Pratt, 2000). International empirical evidence has shown, however, that patenting and licensing are highly concentrated (mainly in chemistry, pharmacy, biotechnology, information technology and engineering: Levin, 1986; Harabi, 1995) and that only a few institutions file many patents (Henderson, Jaffe and Trajtenberg, 1998) and profit from their commercialisation (Bulut and Moschini, 2006). Most universities instead engage with external stakeholders through other channels (Laursen and Salter, 2004; D’Este and Patel, 2007; Bekkers and Bodas Freitas, 2008). Hughes and Kitson (2012) distinguish between knowledge transfer interactions that are people-based (student

placements, employee training, standard-setting forums, network participation), community-based (public exhibitions, community lectures), or aimed at problem-solving (contract research, use of physical facilities, personal and informal advice), commercialisation (patents, licenses, spinoff companies) or consulting. Montesinos et al. (2008) categorise knowledge transfer activities according to their objectives and intended customers (generating income by providing services; transferring technology to businesses; benefitting society). Other classifications distinguish between the provision of research outputs, consulting or education services (Jones-Evans and Klofsten, 2000; Arundel and Geuna, 2004; De Silva, Uyarra and Oakey, 2012).

Relying upon data from the UK, this study explores the institutional and environmental determinants of universities' efficiency in performing a broad range of knowledge transfer activities, and analyses the implications of such broader approach to efficiency measurement. It contributes to a multifaceted debate on: what does 'good' knowledge transfer performance mean; how can universities' relative performance be assessed; what factors help universities to achieve better performance.

The UK provides an interesting case for several reasons. First, this is one of the few countries where extensive data on universities' knowledge transfer activities is collected systematically. The annual Higher Education Business and Community Interaction survey (HEBCI), managed by the UK's Higher Education Statistics Agency (HESA), collects data on universities' engagement in numerous knowledge transfer activities, that are comparable across institutions and over time. Second, the UK has pioneered several national policy instruments that aim to encourage knowledge transfer by rewarding universities' performance. The Higher Education Innovation Fund, introduced in 2001, allocates funds to universities based on the systematic assessment of their knowledge transfer performance, relying on data from

the HEBCI survey. Since 2014, the Research Excellence Framework distributes research funds to universities partly on the basis of an assessment of the socioeconomic impact of their academic research; while primarily directed at improving research quality, this exercise may incentivise universities to more intensively engage in knowledge transfer as a means to achieve broader impact. Policymakers in other countries may look to the UK's innovative policies for guidance in the development of their own approaches (Jensen et al., 2009).

The paper is structured as follows. The next section briefly reviews the literature on universities' efficiency in knowledge transfer, and explores some of the issues that arise when extending the analysis to a broader range of activities. Section 3 introduces the data and the methodology. The results of the empirical analysis are presented in section 4, while section 5 draws some conclusions and implications for management and policy.

## **2. The efficiency of universities' knowledge transfer activities: broadening the framework**

### ***2.1. Current approaches to measuring knowledge transfer efficiency***

In the last two decades, a growing literature has investigated the efficiency of university institutions: Berbegal Mirabent and Solé Parellada (2012), limiting their search to those studies that measured efficiency using non-parametric techniques, identified 45 articles produced between 2001 and 2010. Within this area of investigation, most studies focus on the efficiency of teaching and/or research activities, and only a subset analyse efficient knowledge transfer performance. The latter stream of literature is fragmented and empirically-oriented; data are sourced

from different countries and efficiency is measured with different techniques (Siegel, Veugelers and Wright, 2007). Most of these contributions seek to understand the factors driving the efficient performance of *knowledge transfer offices* (KTOs). In particular, they examine which KTOs best convert the inputs they work with (e.g. new knowledge, new discoveries) into outputs (e.g. licenses) given their resources (staff, funding), and the impact of several institutional and environmental factors on the KTOs' efficiency.

Efficiency studies are usually based on a production function framework, where a frontier of efficient combinations of inputs and outputs is constructed empirically and an organisational unit's technical inefficiency (inability to produce the maximum amount of output given one's inputs, or inability to minimise the use of inputs given one's output) is measured in terms of distance from the frontier. Such frontier can be estimated parametrically using stochastic frontier estimation (SFE; Aigner, Lovell and Smith, 1977; Meeusen and Van den Broeck, 1977) or non-parametrically using data envelopment analysis (DEA; Charnes, Cooper and Rhodes, 1978).

The following table summarises the approaches adopted by studies that investigate the efficiency of universities' KTOs<sup>2</sup>. The methods used include SFE, DEA, and regression analyses on direct measures of performance. The transformation process that is modelled comprises either the commercialisation of research results (Siegel, Waldman and Link, 2003; Chapple et al., 2005; Ken et al., 2009), the embedding of university research findings into IP (Curi, Daraio and Llerena, 2012), the engagement in research contracting, or a combination of these (Rogers, Yin and Hoffmann, 2000; Thursby and Kemp, 2002; Anderson, Daim and Lavoie, 2007; Caldera and Debande, 2012; Berbegal Mirabent, Lafuente and Solé Parellada, 2013; Ho et al., 2014). Hence, the range of knowledge transfer outputs considered includes invention disclosures,

patents applied for and granted, and licenses issued, with a few studies also adding research agreements and spinoff companies.

<<Table 1 about here>>

Both Chapple et al. (2005) and Curi, Daraio and Llerena (2012) find that KTOs exhibit low levels of absolute efficiency, and large inter-organisational variations. KTOs' performance and efficiency are found to depend on the characteristics of the university institution, such as faculty quality, subject specialisation in biological sciences and engineering, private ownership, presence of a medical school or university hospital (Thursby and Kemp, 2002; Anderson, Daim and Lavoie, 2007; Curi, Daraio and Llerena, 2012). University policies, including the definition of clear rules for academics (such as the regulation of potential conflicts of interest and the allocation of a larger proportion of royalties to the inventor) can improve performance by incentivising academics to engage in knowledge transfer (Caldera and Debande, 2012; Link and Siegel, 2005; Friedman and Silberman, 2003; Debackere and Veugelers, 2005; Belenzon and Schankerman, 2007; Lach and Schankerman, 2004). Also important are the economic characteristics of the region where the institution is based, and the characteristics of KTOs, including size, age, management practices, organisational structure (Bercovitz et al., 2001; Siegel, Waldman and Link, 2003; Debackere and Veugelers, 2005).

However, some findings are contradictory. Some studies suggest that having a university hospital or medical school exerts a positive effect on efficiency (Siegel, Waldman and Link, 2003), while others find the opposite (Thursby and Kemp, 2002;

Chapple et al., 2005; Anderson, Daim and Lavoie, 2007; Curi, Daraio and Llerena, 2012). Some find a positive effect of the KTO's size on efficiency (Rogers, Yin and Hoffmann, 2000; Thursby and Kemp, 2002; Caldera and Debande, 2012; Curi, Daraio and Llerena, 2012), while others find a negative effect (Chapple et al., 2005). Siegel, Waldman and Link (2003) find that licensing revenues display increasing returns to scale and that licensing agreements display constant returns, while Chapple et al. (2005) find evidence of decreasing returns. Curi Daraio and Llerena (2014) find that patent filing exhibits variable returns to scale.

While most of these studies aim to identify what determines the efficient performance of KTOs, it is increasingly acknowledged by academics and policymakers alike that knowledge transfer entails varied activities, not all of which are mediated by the university's KTO (Research Councils UK 2007; Hughes and Kitson, 2012). In order to explore universities' efficiency in fulfilling their knowledge transfer mission, the analysis should include a broader range of outputs beyond patenting, licensing, spinoff creation and research contracting with industry.

## ***2.2. Broadening the framework***

Broadening the analysis of knowledge transfer efficiency to include a larger set of knowledge transfer activities is fraught with problems. First, universities fulfil their knowledge transfer mission through many different activities, which may include: delivering knowledge-intensive services, such as consultancies, clinical tests, prototypes, and professional development courses (CPDs); engaging in direct exchanges of knowledge with industry via informal networks and personnel exchanges; contributing to regeneration programmes impacting local communities;

engaging with the public through different mediums; supporting academic spinoffs and graduate start-ups; producing, protecting and licensing IP. Not only this list may be incomplete, but data on some of these activities are very unreliable, when they are collected at all. To complicate matters, it is sometimes difficult to distinguish between knowledge transfer, research and teaching activities.

Second, the outputs of these varied activities cannot all be measured using the same metrics. While some can be measured in terms of the monetary income they produce, not all of them generate income. Moreover, outputs can be very different in terms of quality and impact.

Third, varied types of universities, differing in research intensity, subject specialisation, resources and engagement with their environment, very often have very different knowledge transfer strategies (Deiaco, Hughes and McKelvey, 2012), so it is difficult to identify appropriate terms of comparison. Hewitt-Dundas (2012) shows that British universities with high and low research intensity pursue different knowledge transfer objectives, strategies and activities. The former primarily emphasise collaborations with industry, while the latter prioritise supporting SMEs and developing human capital (widening access to education, retaining graduates in the region and contributing to local skills needs). These different priorities are reflected in their different activities and income sources. Highly research-intensive universities undertake more contract research, collaborative research and licensing, while less research-intensive ones undertake more consultancies and CPDs. The former accrue more income from research councils, international sources and large businesses, while the latter's main sources of income are the national government, SMEs and non-commercial partners. Wright et al. (2008), suggest that, compared with

top universities, mid range universities in the UK, Belgium, Germany and Sweden engage in a broader range of knowledge transfer activities.

Since university departments include staff specialised in closely linked subjects that tend to rely upon similar knowledge transfer channels, they may be more comparable than entire institutions. In fact, several studies of efficiency in research and/or teaching take departments as their units of analysis (Johnes and Johnes, 1993; Chiang and His-Tai, 2006; Agasisti and Bonomi, 2013). However, departmental data on knowledge transfer activities are rarely available, and all the studies that have analysed efficiency in knowledge transfer to date have used institution-level data.

The following Figure 1 presents a conceptual model of knowledge transfer as a process of transformation of generic (teaching and research resources) and dedicated (internal knowledge transfer resources) university inputs, into knowledge transfer outputs. It extends the frameworks previously adopted in the analysis of knowledge transfer efficiency such as those presented by Thursby and Thursby (2002) and Anderson, Daim and Lavoie (2007), in two main ways. First, it considers a broader range of knowledge transfer outputs. While previous studies have focused on IP disclosures and sometimes their further commercial exploitation by means of licensing and spinning off, this model also includes other activities: stipulation of contracts and consultancies, provision of CPDs, public engagement. Second, the model acknowledges that some knowledge transfer outputs, such as spinoffs and licenses, result from a secondary transformation process that uses other knowledge transfer outputs (university IP) as inputs. Often, this secondary transformation process builds upon additional, dedicated inputs: for example, spinoffs rely on dedicated infrastructures like incubators and science parks, as well as on additional sources of seed funding; patenting and licensing operations are often outsourced to external

agencies. In a study that similarly conceptualised knowledge transfer as a two-stage process of research ‘concretisation’ (resulting in patents) and research ‘commercialisation’ (leading to licensing and spinoffs), where the former are inputs for the latter, Ho et al. (2014) found that indeed these are two different transformation processes that build on different capabilities. Since this study aims to analyse the university’s efficiency in transforming internal resources into a broad range of outputs, rather than to track the KTO’s efficiency in protecting and commercialising IP, it focuses on the former process only.

<<Figure 1 about here>>

This simple conceptual model is used, in the next section, to explain the study’s methodological choices in order to measure knowledge transfer efficiency; it does not capture all the complex transformation processes occurring within universities, of which knowledge transfer constitutes only a part, nor all the possible knowledge transfer activities that universities can, in principle, perform.

As a further step, the study also assesses what institutional and environmental factors drive greater efficiency. Institutional factors can affect the efficiency of the university’s knowledge transfer operations, because they constrain the availability of inputs to be deployed in knowledge transfer processes, the manner of their deployment, and the opportunities to generate knowledge transfer outputs. The university’s research intensity matters: the greater the share of resources that a university dedicates to research activities, the more it can - at least according to the established ‘technology transfer’ model based on patenting, contract research and

spinoff creation - generate knowledge outputs that can be transferred to external stakeholders (Antonelli, 2008). For a given amount of generic resources employed, institutions that are more research-intensive can be expected to produce more patents and engage in more contract research with industry partners (Hewitt-Dundas, 2012) and hence enjoy greater efficiency in the production of these outputs. At the same time, opportunities for knowledge transfer also arise from teaching activities (for example, universities can offer CPDs, and support student entrepreneurship), so when a broad range of knowledge transfer outputs is considered, both research-intensive and teaching-intensive institutions can be expected to achieve efficiency, although possibly with different output mixes.

The institutional support provided to knowledge transfer activities can also influence their efficiency. An institution that invests in more and better trained knowledge transfer staff can generate more opportunities for knowledge transfer with the same generic inputs: it has been shown that having more competent and experienced knowledge transfer staff results in better performance (Friedman and Silberman, 2003; Lockett and Wright, 2005; Siegel, Waldman and Link, 2003).

As knowledge transfer entails a variety of activities, universities that engage in a large range of academic subjects can be expected to better capture any opportunities that come along (Wright et al, 2008): given the same inputs, universities with a diversified subject profile should be able to generate more knowledge transfer outputs.

The age, size and subject mix of the university may also matter. Since larger, older institutions often enjoy greater reputation, they can access better quality inputs and enjoy more opportunities to generate outputs. The size of the university is positively related to the level of knowledge transfer (Belenzon and Schankerman, 2009), measured in terms of private research funds (Von Tunzelmann and Kraemer Mbula,

2003), interactions with companies (Bruno and Orsenigo, 2003; Landry, Amara and Ouimet, 2007) and spin-off creation (O'Shea et al., 2005). Subject specialisation can play a role in efficiency, since industry collaborates more frequently with academics in applied sciences like engineering, computer science, biotechnology and medicine (Levin et al., 1987; Schartinger, Schibany and Gassler, 2001; Meyer-Krahmer and Schmoch, 2002; Cohen, Nelson and Walsh, 2002). This is not to say, however, that other academics do not transfer knowledge: academics in the social sciences and arts and humanities engage in public lectures and performances, media involvement, regeneration and community projects (Castro-Martinez, Molas-Gallart and Olmos-Peña, 2010; Olmos-Peña, Castro-Martinez and D'Este, 2011; Hughes and Kitson, 2012).

Environmental factors may affect both the availability of inputs and the opportunities to generate outputs. Since research-intensive firms are more likely to contract out research to universities and rely on academic consultancies, the research intensity of local firms may affect the production of knowledge transfer outputs. The literature has consistently found positive effects on efficiency of various measures of research intensity of local businesses, including level of industrial R&D in the region, rate of growth of private R&D, business R&D expenditure per capita, share of employment in high tech sectors (Chapple et al., 2005; Curi, Daraio and Llerena, 2012; Berbegal Mirabent, Lafuente and Solé Parellada, 2013). Many studies also consider the general economic prosperity of the region, since more prosperous regions are more likely to include better performing firms, and therefore offer more opportunities for knowledge transfer. Here the results have been mixed, with regional economic performance having either positive (Chapple et al., 2005), negative (Curi, Daraio and Llerena, 2012) or no effects (Siegel, Waldman and Link, 2003) on efficiency, suggesting that

the composition of regional industry matters more than overall regional economic performance. Other environmental factors that can influence the efficiency of university institutions are legislation and regulations and public policies supporting knowledge transfer.

### **3. Methodology**

#### ***3.1. Data***

Data for this study is drawn from three sources. The first is the HEBCI survey, which collects information about universities' knowledge transfer infrastructures, strategies and engagement. The HEBCI survey has run since 1999, although it has changed over time so not all variables are available across all years. It currently covers all of the country's 161 institutions, of which 131 are based in England, 16 in Scotland, 10 in Wales and 4 in Northern Ireland; 134 are universities that offer undergraduate, postgraduate and doctoral degrees, while 27 are higher education colleges that do not grant doctoral degrees and are mainly specialised in music, visual and performing arts, or agriculture. The survey includes a broad range of activities spanning collaborative research and regeneration programmes, contract research, consultancies, IP protection and licensing, spin off activities, CPDs, equipment and facilities-related services, and public engagement (public lectures, performances, exhibitions, museum education and other events). It measures a greater variety of knowledge transfer outputs than other well-known surveys, such as the AUTM survey in the US or the NSRC in Australia (Rosli and Rossi, 2015). The second source is the database Heidi, which contains data on universities' financial, human and capital resources, as well as their teaching and research activities. Finally, information on regional gross value

added per capita and regional business R&D expenditure (BERD) has been collected from the UK's Office for National Statistics.

### ***3.2. Empirical strategy***

Efficiency comparisons between different organisations engaging in similar transformation processes are usually performed using either SFE (Aigner, Lovell and Smith, 1977; Meeusen and Van den Broeck, 1977) or DEA (DEA; Charnes, Cooper and Rhodes, 1978). SFE requires the estimation of a production function, where differences in performance across units are attributed to an error term,  $\varepsilon_i$ , which has two components ( $\varepsilon_i = V_i - U_i$ ): statistical noise  $V_i$  (a symmetric, independently and normally distributed random error component) and an inefficiency component  $U_i$ . The latter is a non-negative error term which accounts for the failure to produce the maximum output, given the set of inputs used; it is assumed to be independently and half-normally distributed (as units are either on the frontier or below it). To test the determinants of inefficiency, the term  $U_i$  is then regressed onto a set of independent and control variables. In more recent models (Battese and Coelli, 1995), both the production function (including the inefficiency term) and the determinants of relative inefficiency are estimated simultaneously.

While SFE, as a parametric approach, has several advantages (see Chapple et al., 2005, for a discussion), it can only model single-output production processes. The analysis of processes that involve the simultaneous production of different outputs require to either estimate alternative models (one for each different output, as in Chapple et al., 2005) or aggregate the outputs using a common metrics such as their monetary value, if market prices exist (Ray, 2004).

The other widely used approach to efficiency computation, DEA, consists in numerically computing an efficiency frontier of the best performing units, and positioning the other units in relation to this frontier. This method has been used extensively to compute the efficiency of production processes that generate multiple outputs, some of which may not have easily identifiable market prices, such as in the education sector (Charnes et al., 1994). It is therefore more suitable to computing the efficiency of knowledge transfer processes when not all relevant outputs can be expressed in monetary terms.

Fitting the linear frontier requires identifying, for each combination of inputs used by the observed units, the maximum output that could be produced given that input combination: the set of maximum output/input ratios constitutes the efficient frontier, and the relative efficiency of each unit can be computed by comparing the unit's actual output with the maximum output that could be produced using the same combination of inputs. In practice, this requires solving a linear program: finding the set of weights that maximise each unit's average productivity (ratio of its weighted combination of outputs to its weighted combination of inputs) subject to the constraints that all weights are non-negative and all ratios are smaller or equal to one (maximum efficiency is imposed to be equal to 1).

Once the efficient frontier has been computed, the efficiency of each unit relative to the frontier is measured using a distance function. Usually, inefficiency is presented in terms of a score  $\frac{1}{\lambda} \leq 1$  (Shepherd distance) which identifies the fraction of the unit's actual output to its corresponding optimal output (the maximum output obtainable given the combination of inputs used by the unit): correspondingly, the reciprocal score  $\lambda \geq 1$  (Farrell-Debreu distance) identifies the increase in output that the unit would need to accomplish if it was to become technically efficient.

DEA models come in different specifications. Efficiency can be computed in terms of maximum output that can be produced given a certain combination of inputs (output-oriented model), or of minimum inputs that can be used to produce a given output (input-oriented model). The model can accommodate constant or variable returns to scale. Different types of efficiency frontiers can be fitted: piecewise linear ('convex hull'; Charnes, Cooper and Rhodes, 1978), or staircase shaped ('free disposal hull'; Deprins, Simar and Tulkens, 1984).

This study uses DEA to measure the efficiency of universities' knowledge transfer processes by positioning each university relative to the non-parametric frontier of the most efficient institutions. The choice of outputs and inputs used in the measurement of efficiency follows the model shown in Figure 1, taking into account the availability of reliable and comparable data. Income, when available, is considered as a reliable measure of output: engagement in research contracts, consultancies<sup>3</sup> and CPDs is proxied by the income they accrued. The use of income, rather than just the number of contracts, also accounts for the fact that contracts can differ widely in quality and value. Two further outputs that are not measured in monetary terms are then considered. First, the number of IP disclosures, which include inventions, computer software and databases, literary and artistic works, educational software and multimedia, industrial designs, trademarks, integrated circuit topographies, new plant or animal varieties. This encompassing definition better captures the amount of new IP generated than the simple number of patents filed. Considering the number of disclosures rather than the income generated from their licensing or sale, is not only consistent with the model presented in Figure 1, but also accounts for the fact that some disclosures (such as software released through open source licenses) do not

produce income (Sorensen and Chambers, 2008). Second, outputs include the number of academic staff days employed in public engagement.

Some knowledge transfer outputs are not included in the model. Income from services and equipment-related services is excluded, because this figure comprises room rentals, a service that does not entail transfer of knowledge. Incomes from collaborative research and regeneration and development programmes are also excluded. Both incomes usually derive from public funds allocated competitively, primarily by the research councils and by international and national governmental bodies. The reasons for excluding them are twofold. First, it is not possible to distinguish between income used to support research and income used for knowledge transfer activities. Second, the possibility to access these funds strongly depends on rules issued by the funding bodies (for example, only universities in certain regions may be eligible for regeneration funding), which we are not able to fully control for. It is possible that some forms of regeneration income may be recorded under different headings (such as consultancy or CPD income), although the amounts are likely to be small.<sup>4</sup> Finally, consistent with the model presented in Figure 1, spinoffs are excluded as they generally build upon dedicated resources, hence their cost would not be accounted for in the generic inputs measured.

Inputs comprise several general resources that universities use in the production and transfer of knowledge (research and teaching funds from funding councils grants and from tuition fees, number of academic staff) as well as some specific resources dedicated to knowledge transfer (number of staff employed in knowledge transfer functions). Since there may be a lag between the use of inputs and the production of outputs, five-year averages of the period 2006-2011 are deployed for both inputs and

outputs<sup>5</sup> (averages over several years have also been used by Thursby and Kemp, 2002; Anderson, Daim and Lavoie, 2007; Curi, Daraio and Llerena, 2012).

The dataset includes 160 institutions for which complete five-year data on inputs and outputs exist. The efficiency estimates are computed for a reduced sample of 97 universities that employ strictly positive quantities of all the inputs and outputs considered, to allow comparability. The 97 universities included in the sample do not have a significantly different geographical distribution than the 63 that have been excluded. However, they differ in respect to several institutional characteristics. Those that have been excluded are on average significantly younger, have younger KTOs and are less likely to have a university hospital. They have a significantly lower average share of academic staff in the natural sciences, medicine, engineering and technical subjects, and the social sciences, and a higher average share of academic staff in the arts and humanities. In fact, many institutions that have a high share of staff in the arts and humanities (which include most higher education colleges) do not generate IP disclosures (this was the case for 52 out of these 63 institutions; of the remaining 11, 9 did not report any days spent on public engagement, 1 did not report any consultancy income and 1 did not report any income from research contracts).

Table 2 describes the input and output variables used to compute the universities' efficiency, and reports their main descriptive statistics. The correlation matrix between inputs and outputs is reported in Appendix A.

<<Table 2 about here>>

The empirical strategy involves, first, checking whether the adoption of a broad approach to measuring the efficiency of the knowledge transfer transformation process produces sensibly different results compared with the adoption of a narrow approach that only considers the creation of new IP and contracts with industry. Several knowledge transfer inputs are used, at the same time, for research and teaching – for example, the time of academic staff and the funds from government grants and tuition fees. Therefore, it is not possible to precisely identify how much of these inputs goes in the production of knowledge transfer outputs; as Thursby and Kemp (2002) note, we would not be able to say whether a university that has a higher number of patent applications than another, vis-à-vis a given amount of inputs, is more efficient than the latter or is simply allocating more of its inputs to activities that are more likely to produce patentable outputs. However, using a broad definition of knowledge transfer should mitigate this problem: since the range of knowledge transfer outputs considered draws upon a wide variety of university resources, universities could allocate their inputs differently among teaching and research, or among the social and natural sciences, and still enjoy similar opportunities for knowledge transfer. It should then be possible to observe an increase in the relative efficiency of universities that allocate more inputs to activities that do not fit well with the model of technology transfer based on the commercialisation of IP and the performance of contract research.

To check whether this is the case, the DEA efficiency scores of universities are computed under two different model specifications: a narrow model which includes only two outputs capturing universities' efficiency in technology transfer (number of IP disclosures and income from research contracts) and a broad model which includes five outputs (number of IP disclosures, income from research contracts, consultancies

and CPDs, and number of academic staff days employed in public engagement). The efficiency scores, in both models, are computed using the output-oriented<sup>6</sup> DEA linear program with non-increasing returns to scale<sup>7</sup> implemented in the rDEA package for R Cran. Having ranked universities according to their efficiency scores in each model, it is then possible to examine the characteristics of the universities that improve their relative rank positions<sup>8</sup> in the broad model of knowledge transfer, compared to the narrow one.

The second step involves exploring the institutional and environmental determinants of efficiency, focusing on the broad model of knowledge transfer. Two alternative dependent variables are used. The first dependent variable is an indicator variable called *INEFFICIENT* that takes on value 1 if the university is inefficient and zero otherwise (as in Thursby and Kemp, 2002).<sup>9</sup> The regressors used in this logit model (Model 1) capture a varied range of institutional and environmental factors:

- research intensity is measured as the ratio of public research funding grants to academic staff, *Public research funds per academic staff*); teaching intensity is measured as the number of *Students per academic staff* (including undergraduate, postgraduate and research students);
- the age of the institution's KTO (*KTO age*) is used a proxy for the experience of the institution with knowledge transfer;
- the subject diversification of academic staff (measured as the inverse of the Herfindahl index on the shares of academic staff in each of four main subject areas - natural sciences and medicine, engineering and technology, social sciences and business, arts and humanities) quantifies how broad is the range of subjects that the university offers, and the relative weight of each subject: the more ‘equal’ the subject shares, the higher is the index. A low value

- implies that the university is more specialised while a higher value implies that the university is more diversified (*Subject diversification*);
- regional gross value added per capita in 2006 (variable *Regional GVA*) and level of business R&D spending in the region in 2006 (variable *Regional BERD*) capture the opportunities offered by the university's economic environment; the number of other universities in the same city is used to proxy the intensity of competition among them (variable *City Universities*);
  - several controls are also included: the age of the institution (*Age*), its size in terms of total staff (*Size*), whether a university hospital is present (*University hospital*), the shares of academic staff in the natural sciences and medicine (*Science and medicine*), technical and engineering subjects (*Technical*), the social sciences and business (*Social*) and the arts and humanities (*Arts and Humanities*), the country (*England, Scotland, Wales or Northern Ireland*). As the universities in the sample are all public, ownership is not controlled for.

The regressors refer to 2006/07 because the aim is to test the effect of institutional and environmental variables, which affect both inputs and outputs, on efficiency measured with respect to the subsequent five years.

The second dependent variable is the efficiency score (in the Farrell-Debreu distance formulation; higher score indicates greater distance from the efficient frontier, therefore greater inefficiency) obtained by the institution (Model 2). In order to perform inference on the determinants of the efficiency of different institutions, numerous studies have used two-stage estimations, whereby efficiency scores are estimated in the first stage and then regressed using OLS or Tobit models on several institutional and environmental variables in the second stage (an overview is presented in Simar and Wilson, 2007). However, it has been pointed out that the DEA

efficiency scores are serially correlated, which invalidates standard approaches regarding statistical inference (Simar and Wilson, 2000). The bias correction procedure suggested by Simar and Wilson (2007)<sup>10</sup> is therefore used to perform inference on the efficiency scores.

## 4. Empirical results

### ***4.1. Comparison of universities' rank positions under the narrow and broad models of knowledge transfer***

Universities have been ranked according to their efficiency scores computed under the narrow and the broad models of knowledge transfer. 31 universities improve their rank position in the broad model compared to the narrow model, while 66 universities either maintain or worsen their rank position. In the broad model, more universities achieve efficiency (ten instead of five), mean efficiency is higher (0.49 instead of 0.33) and the distribution of efficiency scores is less skewed (skewness is 0.67 instead of 1.07).

Universities that improve their rank position in the broad model have a lower share of staff in medicine and natural sciences and a higher share of staff in the arts and humanities, and are less likely to have a university hospital, than those that do not improve their position (Table 3). This supports the conjecture that universities that allocate more inputs to activities that do not fit well with the established technology transfer model based on patents and research contracts (which is particularly suited to medicine, biotechnology and a few other technical fields, but not relevant to all subject areas), do better when a broader set of outputs is considered. Also, universities that improve their rank position in the broad model have fewer public research funds

per academic and more students per academic, consistently with literature suggesting that less research-intensive universities have a broader knowledge transfer portfolio (Hewitt-Dundas, 2012; Wright et al., 2008). Considering the differences across mean amounts of inputs and outputs in the two groups, the universities that improve their rank position deliver significantly more days of public events and receive significantly more income from CPDs (but significantly less income from research contracts) than those that do not improve their position. This confirms that their improved efficiency is due to their ability to engage in a varied portfolio of activities that is not taken into account when considering only a narrow range of outputs.

<<Table 3 about here>>

#### ***4.2. Inputs, outputs and their relationship with efficiency***

The remaining part of the analysis explores the institutional and environmental determinants of efficiency considering the broad model of knowledge transfer. There are ten efficient universities and 87 inefficient ones. Consistently with findings by Chapple et al. (2005) and Curi, Daraio and Llerena (2012), the analysis of the efficiency scores shows low levels of absolute efficiency (the mean efficiency score is 0.49) and marked variability between universities (standard deviation is 0.22).

To explore the relationship between inputs, outputs and efficiency, inputs and outputs are regressed on the indicator variable *INEFFICIENT*. The logit regression in Table 4 (column (1)) shows that inputs have, as expected, a significantly positive relationship with inefficiency (except for the number of academic staff which is not significant). Outputs have, as expected, a negative relationship with inefficiency (although income

is not significant). As a robustness check, the same regression is run only using the significant variables in column (1) (column (2)), which confirms their signs and significance. Therefore inefficient universities produce significantly less outputs (especially IP disclosures and public engagement) than efficient ones, while using relatively more generic funds for research and teaching and more dedicated knowledge transfer staff.

<<Table 4 about here>>

#### ***4.3. The institutional and environmental drivers of efficiency***

The institutional and environmental variables, as well as several control variables, are then regressed on, separately, the *INEFFICIENT* variable (Model 1) and the efficiency scores (Model 2). Table 5 reports the main descriptive statistics on the variables used in the regressions. The correlations between the regressors are reported in Appendix B.

<<Table 5 about here>>

The results of the regressions on the *INEFFICIENT* variable are shown in columns (1a) and (1b) of Table 6. The results of the regressions on the efficiency scores are shown in columns (2a) and (2b) of Table 6.

<<Table 6 about here>>

The variables' signs and significance are broadly similar across both models. The regressions under Model 1 report generally weaker correlations, due to the relatively lower variability in the dependent variable and particularly the fact that only a few universities are efficient.

The variables *Public research funds per academic staff*, and *Students per academic staff* are not significant. This supports the previous conjecture that, when the broader model of knowledge transfer is considered, opportunities for knowledge transfer arise from both research and teaching activities, and research intensity is not a strong requirement to achieve efficiency<sup>11</sup>. Universities that have lower research intensity can achieve efficient performance in delivering a broad set of knowledge transfer outputs, while this would not be the case if only a narrow set of outputs was considered.

Having an older KTO increases inefficiency (contrary to the findings by Curi, Daraio and Llerena, 2012, on the French university system). Empirical studies have suggested that what improves the performance of KTOs are the professionalisation and qualifications of its staff as well as the adoption of supportive policies and procedures (Siegel, Waldman and Link, 2003; Debackere and Veugelers, 2005; Caldera and Debande, 2012), rather than the simple establishment of a KTO. Universities whose KTOs are older may even be disadvantaged to the extent that the presence of an older structure may discourage experimentation with new, more appropriate policies and practices.

Although universities with a diversified subject profile were expected to enjoy greater opportunities for knowledge transfer, the results instead suggest that a higher degree

of subject diversification is associated with greater likelihood to be inefficient. This may be due to more specialised universities enjoying greater prestige in their subject areas and thus being able to command higher income from (and greater opportunities for) knowledge transfer. It may also suggest that the skills and structures needed to support knowledge transfer are subject-specific, so that supporting knowledge transfer in a range of subjects simultaneously does not generate positive synergies, while being able to focus resources in one subject area generates greater returns. To shed further light on this relationship, in models (1b) and (2b) we include the square of *Subject diversification*. The sign and significance of the coefficient suggest that the relationship between subject diversification and inefficiency is inverse-U shaped, with both very specialised and very diversified universities being less inefficient.

The level of BERD and number of universities in the same city significantly increase inefficiency. The positive sign of the latter variable is probably due to increased competition, both for good quality inputs and for knowledge transfer opportunities, among institutions that are close to each other. The effect of the level of BERD contrasts with findings from other studies that have found that higher BERD increases efficiency. This suggests that when knowledge transfer is not considered only in terms of patent commercialisation, the external stakeholders involved go beyond R&D-intensive firms, and regions with a different composition of economic activity may also offer opportunities for knowledge transfer.

In terms of control variables, older and larger universities are less likely to be inefficient, in line with other studies. These universities may enjoy greater opportunities for knowledge transfer thanks to their prestige, visibility and reputation. The presence of a university hospital has a weakly positive effect on the university's inefficiency, consistently with findings from other studies that use European data

(Chapple et al., 2005; Anderson, Daim and Lavoie, 2007; Curi, Daraio and Llerena, 2012). A possible interpretation is that knowledge transfer outputs arising from medical research performed in university hospitals are assigned to the hospital directly, and go unreported by the university.

## **5. Conclusions**

This study has several implications for university management and for policymakers in the science, technology, innovation and education policy domains.

In terms of management implications, the findings suggest that universities with different production models can be equally efficient in generating knowledge transfer outputs, and that research intensity is not a pre-requisite for efficiency. Universities can achieve efficiency by adopting a model of knowledge transfer engagement that is consistent with their resources (their subject specialisation, their research and teaching intensity, their knowledge transfer capabilities and infrastructures) without needing to replicate the knowledge transfer strategies of prominent institutions whose resources may be very different. Managers should therefore invest effort in identifying the knowledge transfer engagement strategies that best fit the institution's resources, and aim to increase their performance in those activities. This approach may also improve the university's reputation for excellence in specific knowledge transfer activities, which in turn may increase their ability to generate further knowledge transfer outputs. In fact, institutional reputation appears to increase knowledge transfer opportunities, with more reputable older, larger and very diversified institutions achieving greater efficiency.

Another management implication is that, rather than having an established KTO, what matters for efficiency are its practices and policies, and the professionalisation of its staff. KTOs therefore need to invest in staff training and in the development of best practices. Developing specialised, subject-specific skills and structures to support knowledge transfer, rather than generic ones, may also pay off, as suggested by the finding that more specialised universities are more efficient.

In terms of policy implications, the findings suggest that performance assessment systems need to adopt a broader definition of knowledge transfer. With a broader approach, more universities achieve efficiency, mean efficiency is higher, and the distribution of efficiency scores is less skewed. The universities that improve their efficiency typically have more arts and humanities staff, and less staff in the natural sciences and medicine; they also tend to be less research- and more teaching-intensive. Therefore, systems of performance measurement that rely on a narrow definition of knowledge transfer tend to underestimate the efficiency of universities that do not follow the standard technology transfer model. In this vein, a criticism moved to the UK's approach to knowledge transfer funding concerns the use of income as a measure of performance. This approach rewards universities whose knowledge transfer outputs are best measured in monetary terms, but this is unlikely to suit all university institutions, for example those whose prevailing form of knowledge transfer is public engagement. As our analysis shows, measuring performance with different outputs produces different efficiency rankings.

As the understanding of the complexity of universities' knowledge transfer processes grows, the development of systems to assess their performance should also increasingly reflect this complexity, and allow for a more comprehensive assessment of knowledge transfer engagement. This is not easy to achieve. Although adopting a

broader model of knowledge transfer increases comparability among universities with different knowledge transfer strategies, methodological and data availability issues impose several constraints: the efficiency analysis could be performed only on the 97 universities that use positive quantities of all the inputs and outputs considered (which led to the exclusion of certain types of institutions such as most higher education colleges), and some knowledge transfer outputs were left out for data availability reasons. One way to achieve greater comparability of the assessed units would be to carry out efficiency analyses at departmental level, but few knowledge transfer data are systematically collected from university departments. Another approach might be to group universities according to the model of knowledge transfer they adopt, and then compare the relative performance of universities within each group (considering appropriate input and output mixes), rather than rate all universities against all others.

Finally, while performance is often measured by looking at outputs, thinking about performance in terms of efficiency helps to recognise that universities work with very different resource mixes, which affect the nature of their knowledge transfer engagement. Changes in the resources available to universities, for example because of changes in the rules governing the allocation of public funds, will also change their ability to engage in knowledge transfer. Therefore, policymakers need to think systematically about the effect of changes in funding for research and teaching (for example, the replacement of recurrent grants with competitive funding) on the universities' ability to engage in knowledge transfer. The relationship between nature of funding sources and knowledge transfer strategies, which so far has been largely unexplored, would merit greater attention from both researchers and policymakers.

<sup>1</sup> Dedicated public funds for knowledge transfer engagement, where they exist, are usually small compared to public funding for research and teaching; for example, in England in 2014/15, funding allocated to support universities' knowledge transfer activities (160 million GBP) amounted to about 5% of the recurrent grants allocated for teaching and research (3.1 billion GBP) (Higher Education Funding Council for England, 2016).

<sup>2</sup> These studies have been identified based on the reviews by Berbegal Mirabent and Solé Parellada (2012), Oliveira and Teixeira (2010), Siegel, Veugelaers and Wright (2007), and a further search for articles on Google Scholar using the keywords "university" AND "efficiency" AND "technology transfer" OR "knowledge transfer".

<sup>3</sup> Consultancy income is a problematic variable since university policies vary: when academics are allowed to engage in private consulting, at least to some extent, the related incomes are unreported, leading to an underestimation of the real amount of consulting performed. This problem is mitigated by the fact that, in recent years, most universities have simultaneously tightened the rules on academic consulting and increased the incentives for academics to declare their consulting activities to the university. Providing consulting activities through the universities rather than privately has been made safer (most universities offer free indemnity insurance policies) and easier (most universities now have a contracting system for staff consulting activities; Perkmann and Walsh, 2007).

<sup>4</sup> I am grateful to an anonymous reviewer for this remark.

<sup>5</sup> Since DEA scores are robust with respect to the inclusion of highly correlated inputs (as it is the case with all the inputs used in this study), the results would not change substantially if lagged inputs were used instead (Anderson, Daim and Lavoie, 2007).

<sup>6</sup> The output-oriented approach is appropriate because universities are more interested in maximizing knowledge transfer outputs than in minimizing the inputs used in the knowledge transfer production process: in fact, most inputs are concurrently deployed in the production of research and teaching, so, for the purpose of knowledge transfer, they can be considered as exogenously determined and (almost) fixed in the short term.

<sup>7</sup> For both the narrow and the broad models the null hypothesis of constant returns to scale versus the alternative hypothesis of variable returns to scale was rejected at 5% significance level (according to the test statistic proposed by Simar and Wilson, 2011), while the null hypothesis of non-increasing

---

returns to scale versus the alternative hypothesis of variable returns to scale could not be rejected at this significance level. These tests were implemented using the rts.test routine included in the package rDEA for R-Cran.

<sup>8</sup> It is not possible to directly compare the universities' efficiency scores under the two models, as their magnitude is only meaningful in a relative sense.

<sup>9</sup> This variable has been constructed to represent inefficiency, rather than efficiency, for consistency with our analysis of efficiency scores, whose bias-correction procedure has been developed using the Farrell-Debreu distance measure (Simar and Wilson, 2007).

<sup>10</sup> This has been implemented using the dea.env.robust routine included in the package rDEA for R-Cran.

<sup>11</sup> As a robustness check, the same variables in models (2a) and (2b) have been regressed on the efficiency scores computed using the narrower set of inputs (IP disclosures and research contracts): in this case, research intensity significantly reduces inefficiency (in line with previous studies that have considered a narrower model of knowledge transfer), while teaching intensity has a positive, but not significant, relationship with inefficiency.
