Abstract

We study a method for key predistribution in a network of n users where pairwise keys are computed by hashing users' IDs along with secret information that has been (pre)distributed to the network users by a trusted entity. A communication graph G can be specified to indicate which pairs of users should be able to compute keys. We determine necessary and sufficient conditions for schemes of this type to be secure. We also consider the problem of minimizing the storage requirements of such a scheme; we are interested in the total storage as well as the maximum storage required by any user. Minimizing the total storage is NP-hard, whereas minimizing the maximum storage required by a user can be computed in polynomial time.

1 Introduction

Suppose we have a network of n users and we want every pair of users to have a secure *pairwise key*. When keying information is distributed “ahead of time” by a trusted authority, we have a *key predistribution scheme*, or *KPS*. The *trivial* KPS assigns $n - 1$ distinct pairwise keys to each user, so we say that each user has *storage* equal to $n - 1$. The *total storage* in the trivial scheme is $n(n - 1)$, since each of the n users has storage equal to $n - 1$. Assuming the pairwise keys are chosen independently and uniformly at random from a specified keyspace, the trivial scheme is secure against (maximum size) coalitions of size $n - 2$, since each pairwise key is known only to two participants and cannot be computed even if all the remaining $n - 2$ participants collude.

An interesting way to reduce the storage requirement, as compared to the trivial scheme, is to use a *Blom Scheme* [3]. The Blom Scheme incorporates a *security parameter* denoted by k ; pairwise keys are unconditionally secure against coalitions of up to k users. Each user's storage requirement in the Blom Scheme is $k + 1$ and this storage requirement is shown to be optimal by Blundo *et al.* [4].

*D. Stinson's research is supported by NSERC discovery grant 203114-11

Another approach, due to Lee and Stinson [7], is called an *ID-based one-way-function key predistribution scheme*, also known as *IOS*. Here, pairwise keys are computed by hashing public information along with secret information. This technique can be used to construct a secure scheme in which every pair of n users has a pairwise key. Here we obtain security against maximum size coalitions, but the security depends on the hash function used to construct the keys. We will assume that the hash function can be modelled as a random function, i.e, the security analysis will be done in the standard *random oracle model* [2]. The storage requirement of this scheme is reduced by almost half as compared to the trivial scheme. In [5], a very similar scheme was described that has the same storage requirement as IOS.

It is also possible to consider a more general setting where we specify a *communication graph* G consisting of all the pairs of users who we want to be able to share a secret key. A trivial KPS for a given communication graph G would assign $\deg(u)$ keys to vertex u , for every vertex u in G , where $\deg(u)$ denotes the degree of vertex u . In the case of unconditionally secure schemes secure against coalitions of size k , Blundo *et al.* [4] gave a construction where a vertex u has storage requirement $\min\{k + 1, \deg(u)\}$, for every vertex u . Lee and Stinson’s construction [7] applies to regular graphs of even degree d ; the storage requirement for each vertex is $1 + d/2$.

1.1 Our contributions

In Section 1.2, we introduce some graph-theoretic terminology and basic results that are required later in the paper. In Section 2, we define a general model for IOS for a specified communication graph G . In Section 2.1, we determine necessary and sufficient conditions for an IOS to be secure. Our characterization of secure IOS involves certain *key graphs*. We then use our characterization of secure IOS to investigate the storage requirements of these types of schemes. We show in Section 2.2 that it is sufficient to restrict our attention to schemes obtained by decomposing the edges of the communication graph into “stars”. In Section 3.1, we investigate how to minimize the total storage in the scheme. In general, this turns out to be equivalent to determining the size of a maximum independent set of vertices in G , which is an NP-hard problem. For complete graphs, however, it is easy to give an exact answer. In Sections 3.2 and 3.3, we turn to the problem of minimizing the maximum storage required by any vertex of G . We give a complete solution for regular graphs. For arbitrary graphs, we can show that the optimal maximum storage can be determined in polynomial time by exploiting a connection with the *minimum maximum indegree* problem. In Section 4, we discuss our results in comparison to the recent paper by Choi, Acharya and Gouda [5].

1.2 Graph-theoretic terminology

Definition 1.1. A *graph* is a pair $G = (V, E)$ where V is a finite set of *vertices* and E is a set of *edges*, where every edge is a set of two vertices. We say that the edge $e = \{u, v\}$ *joins* the vertices u and v , and u and v are *incident with* e . We may also write an edge $\{u, v\}$ as uv . If E is instead a multiset, then we say that $G = (V, E)$ is a *multigraph*.

Definition 1.2. For a vertex u in a graph G , The *degree* of $u \in V$, denoted $\deg(u)$, is the number of edges that are incident with u . A graph is *m -regular* if every vertex has degree equal to m .

For a graph $G = (V, E)$, we will denote the number of vertices (i.e., $|V|$) by n and the number of edges (i.e., $|E|$) by ϵ .

Definition 1.3. Suppose $G = (V, E)$ is a graph and $u, v \in V, u \neq v$. A (u, v) -path is a sequence of the form $v_1, e_1, v_2, e_2, \dots, e_\ell, v_{\ell+1}$, where $v_1, \dots, v_{\ell+1} \in V$ are distinct vertices, $e_1, \dots, e_\ell \in E$, $v_1 = u, v_{\ell+1} = v$, and e_i is incident with v_i and v_{i+1} for $1 \leq i \leq \ell$.

Definition 1.4. A graph is *connected* if, for all distinct vertices u and v , there exists a (u, v) -path.

Definition 1.5. A *directed graph* is a pair $G = (V, E)$ where V is a finite set of *vertices* and E is a set of *directed edges*, where every edge is an ordered pair of two distinct vertices. The *indegree* of a vertex $v \in V$ is the number of directed edges $(u, v) \in E$. The *outdegree* of a vertex $v \in V$ is the number of directed edges $(v, u) \in E$.

Definition 1.6. A connected graph (or multigraph) $G = (V, E)$ has an *eulerian circuit* if there exists a circuit in which every edge is used exactly once. It is well-known that a connected (multi)graph has an eulerian circuit if and only if every vertex has even degree.

Definition 1.7. A *complete graph* K_n is a graph on n vertices where every pair of vertices are joined by an edge.

Definition 1.8. A *complete bipartite graph* K_{n_1, n_2} is a graph on $n_1 + n_2$ vertices $V = V_1 \cup V_2$, where $|V_1| = n_1, |V_2| = n_2$, and $E = \{\{v_1, v_2\} : v_1 \in V_1, v_2 \in V_2\}$.

Definition 1.9. A *star* is a complete bipartite graph $K_{1, m}$ for some $m \geq 1$. If $m > 1$, then the *centre* of the graph is the (unique) vertex of degree m . If $m = 1$, then the graph is a single edge and we can specify either endpoint to be the centre of the star. Vertices in a star that are not the centre will be termed *leaves*. A *directed star* is obtained from a star by directing every edge from the leaf to the centre.

Definition 1.10. Given a graph $G = (V, E)$, an *independent set* is a subset of vertices $V_0 \subseteq V$ such that $\{u, v\} \notin E$ for every $u, v \in V_0$. The size of a maximum independent set of vertices in a graph G is denoted by $\alpha(G)$.

Theorem 1.1 (Rosenfeld [8]). *In any m -regular graph $G = (V, E)$, we have*

$$\alpha(G) \leq \min\{\lfloor n/2 \rfloor, n - m\},$$

where $n = |V|$.

Definition 1.11. Given a graph $G = (V, E)$, the *complement* of G is the graph $\overline{G} = (V, \overline{E})$, where $\{u, v\} \in \overline{E}$ if and only if $\{u, v\} \notin E$, for every $u, v \in V, u \neq v$.

Definition 1.12. Let $G = (V, E)$ and $H = (W, F)$ be graphs, where $V \cap W = \emptyset$. The *join* of G and H , is the graph denoted as $G \vee H$. The vertex set of $G \vee H$ is $V \cup W$. The edges of $G \vee H$ consist of all edges in E or F , and all $\{v, w\}$ with $v \in V$ and $w \in W$.

Definition 1.13. Let $G = (V, E)$ be a graph and let $W \subseteq V$. The *subgraph of G induced by W* is the graph $H = (W, F)$, where $F = \{\{u, v\} \in E : u, v \in W\}$.

2 A general model for ID-based one-way-function KPS

In an ID-based one-way-function key predistribution scheme (or IOS), pairwise keys are constructed by hashing public information along with secret information. We describe a general model for IOS for a given communication graph $G = (V, E)$ on n vertices. We identify the n vertices in V with a set of n users, say \mathcal{U} . Our first goal is to obtain a KPS in which two users $u, v \in \mathcal{U}$ have a pairwise key $L_{u,v}$ whenever $\{u, v\} \in E$. Security of the scheme will be addressed in Section 2.1.

Let $f: E(G) \rightarrow \{1, \dots, t\}$ be a publicly known surjective function and let $R_1, \dots, R_t \in \{0, 1\}^\sigma$ be secret values chosen uniformly at random from $\{0, 1\}^\sigma$. Let $h: \{0, 1\}^* \rightarrow \{0, 1\}^\sigma$ be a hash function (which we model as a random oracle). The length of the R_i 's, namely σ , is the same as the length of the output of h . A suitable value for σ is $\sigma = 128$. The function h will be used as a *key derivation function*.

Every pairwise key $L_{u,v}$ will be computed as

$$L_{u,v} = L_{v,u} = h(R_{f(\{u,v\})} \parallel \text{ID}(u) \parallel \text{ID}(v)), \quad (1)$$

where

- (1) for every $u \in \mathcal{U}$, $\text{ID}(u)$ denotes public identifying information for user u , and
- (2) $u < v$ (this requirement ensures that $L_{u,v} = L_{v,u}$ in (1)).

Suppose a value $R_{f(\{u,v\})}$ is not known to a coalition of users. Recall that $R_{f(\{u,v\})}$ was chosen uniformly at random from a set of size 2^σ . Also, the key $L_{u,v}$ is the output of a random function h that takes on values from a set of size 2^σ . Therefore this key can be regarded as a secure σ -bit key.

Eventually, we will investigate whether secret values may be “repeated”, i.e., used for the computation of more than one key, without compromising security. The motivation is that this might enable the storage of the scheme to be reduced. This question will be addressed in Section 2.1.

Remark 2.1. As described above, the public inputs to the hash function are taken to be (public) IDs. Actually, it doesn't really matter what the public inputs to h are, as long as there do not exist two keys that have the same public and secret inputs and we ensure that $L_{u,v} = L_{v,u}$.

It is obvious that if $\{u, v\} \in E$ and $f(\{u, v\}) = j$, then users u and v each must store one of R_j or $L_{u,v}$. We will assume that neither u nor v stores both R_j and $L_{u,v}$, since $L_{u,v}$ can be computed if R_j is known.

Definition 2.1. For $1 \leq j \leq t$, define

$$E_j = f^{-1}(j) = \{\{u, v\} \in E : f(\{u, v\}) = j\}$$

and let V_j be the vertices spanned by E_j . (V_j, E_j) is a graph that we term the *j*th key graph.

Let

$$W_j = \{v \in V_j : v \text{ stores } R_j\}$$

and define $\mathcal{W} = (W_1, \dots, W_t)$. Since we are assuming that f is surjective, it follows that $|E_j| \geq 1$ and $|V_j| \geq 2$ for all $j \in \{1, \dots, t\}$.

An IOS is fully specified by f and \mathcal{W} , so we will refer to (f, \mathcal{W}) as a *G-IOS*.

To summarize, here is all the keying information that is stored in a G -IOS, (f, \mathcal{W}) . Suppose $u \in V$ is any vertex and $\{u, v\} \in E$ is any edge that is incident with u . If $\{u, v\} \in E_j$, then the vertex u stores R_j when $u \in W_j$, and it stores $L_{u,v}$, otherwise.

Example 2.1. Consider the graph $G = (V, E)$, where

$$V = \{1, 2, 3, 4, 5\} \text{ and } E = \{12, 13, 14, 15, 23, 25, 34, 45\}.$$

Suppose we define

$$\begin{aligned} f(12) = f(13) = f(14) &= 1 & W_1 &= \{1\} \\ f(15) = f(25) = f(45) &= 2 & W_2 &= \{5\} \\ f(23) = f(34) &= 3 & W_3 &= \{3\}. \end{aligned}$$

Then it is easy to see that

$$\begin{aligned} E_1 &= \{12, 13, 14\} & V_1 &= \{1, 2, 3, 4\} \\ E_2 &= \{15, 25, 45\} & V_2 &= \{1, 2, 4, 5\} \\ E_3 &= \{23, 34\} & V_3 &= \{2, 3, 4\}. \end{aligned}$$

The keying material held by each user is as follows:

user 1 stores $R_1, L_{1,5}$
user 2 stores $L_{1,2}, L_{2,3}, L_{2,5}$
user 3 stores $R_3, L_{1,3}$
user 4 stores $L_{1,4}, L_{3,4}, L_{4,5}$
user 5 stores R_2 .

■

2.1 Secure IOS

Suppose that (f, \mathcal{W}) is a G -IOS. We say that (f, \mathcal{W}) is *secure* if there does not exist a user w who can compute a key $L_{u,v}$ where $\{u, v\} \in E$ and $w \neq u, v$. This security condition will be satisfied provided that w does not know either of the values R_j or $L_{u,v}$ (where $j = f(\{u, v\})$). Note that a secure IOS is automatically secure against maximum size coalitions.

We now consider when a G -IOS, as defined above, will be secure. We prove a sequence of simple lemmas that culminate in a characterization of secure G -IOS. The first lemma is obvious.

Lemma 2.1. *Suppose (f, \mathcal{W}) is a G -IOS, $\{u, v\} \in E$ and w stores $L_{u,v}$, where $w \neq u, v$. Then (f, \mathcal{W}) is not secure.*

Lemma 2.2. *Suppose (f, \mathcal{W}) is a secure G -IOS and w stores R_j . Then $w \in V_j$.*

Proof. Suppose w stores R_j but $w \notin V_j$. Let $\{u, v\} \in E_j$; then $w \neq u, v$ because $w \notin V_j$. But then w can compute $L_{u,v}$, so (f, \mathcal{W}) is not secure. \square

Lemma 2.3. *Suppose (f, \mathcal{W}) is a G -IOS and $\{u, v\}, \{u, v'\} \in E_j$, where $v \neq v'$. If $v \in W_j$ or $v' \in W_j$, then (f, \mathcal{W}) is not secure.*

Proof. If $v \in W_j$, then v can compute $L_{u,v}$. Similarly, if $v' \in W_j$, then v' can compute $L_{u,v}$. \square

Lemma 2.4. *Suppose (f, \mathcal{W}) is a G -IOS and $\{u, v\}, \{u', v'\} \in E_j$, where $\{u, v\} \cap \{u', v'\} = \emptyset$. If $\{u, u', v, v'\} \cap W_j \neq \emptyset$, then (f, \mathcal{W}) is not secure.*

Proof. If $u \in W_j$, then u can compute $L_{u',v'}$. If $v \in W_j$, then v can compute $L_{u',v'}$. If $u' \in W_j$, then u' can compute $L_{u,v}$. If $v' \in W_j$, then v' can compute $L_{u,v}$. \square

Lemma 2.5. *Suppose (f, \mathcal{W}) is a secure G -IOS and $u, v \in W_j$. Then the key graph E_j consists of a single edge $\{\{u, v\}\}$.*

Proof. First suppose that $\{u, v\} \notin E_j$. Suppose $\{u, u'\} \in E_j$ and $\{v, v'\} \in E_j$. If $u' \neq v'$, then Lemma 2.4 is contradicted. If $u' = v'$, then Lemma 2.3 is contradicted. Therefore it follows that $\{u, v\} \in E_j$. Suppose that there is some other edge $\{u', v'\} \in E_j$. If $\{u, v\} \cap \{u', v'\} = \emptyset$, then Lemma 2.4 is contradicted. Otherwise, suppose without loss of generality that $u = u'$. Then Lemma 2.3 is contradicted. \square

Lemma 2.6. *Suppose (f, \mathcal{W}) is a secure G -IOS. Then, for every j , $|W_j| = 0, 1$ or 2 .*

Proof. Suppose $|W_j| \geq 3$ and suppose W_j contains three distinct elements u, v, w . We now apply Lemma 2.5: since $u, v \in W_j$, we have that $E_j = \{\{u, v\}\}$. Furthermore, since $u, w \in W_j$, we have that $E_j = \{\{u, w\}\}$. This is impossible because $v \neq w$. \square

Lemma 2.7. *Suppose (f, \mathcal{W}) is a secure G -IOS. If $|W_j| = 1$, say $W_j = \{v\}$, then the j th key graph is a star with centre v .*

Proof. Suppose there is an edge $\{u, u'\} \in E_j$ where $v \neq u, u'$. Then v can compute $L_{u,u'}$. \square

The above conditions are necessary for a G -IOS, say (f, \mathcal{W}) , to be secure; we now show that they are also sufficient to provide security.

Theorem 2.8. *Suppose (f, \mathcal{W}) is a G -IOS. Then (f, \mathcal{W}) is secure if and only if the following conditions hold:*

- (1) $|W_j| \leq 2$ for all j ;
- (2) for any j with $|W_j| = 1$, say $W_j = \{v\}$, the j th key graph is a star with centre v ; and
- (3) for any j with $|W_j| = 2$, say $W_j = \{u, v\}$, the j th key graph consists of the single edge $\{\{u, v\}\}$.

Proof. These three conditions are shown to be necessary for (f, \mathcal{W}) to be secure in Lemmas 2.5–2.7. We now show they are sufficient for the scheme to be secure. Suppose the three conditions hold but (f, \mathcal{W}) is not secure. We will obtain a contradiction.

If (f, \mathcal{W}) is not secure, then some user $w \neq u, v$ can compute a key $L_{u,v}$ where $\{u, v\} \in E$. Let $f(\{u, v\}) = j$. Since w does not store $L_{u,v}$ (Lemma 2.1), it follows from Lemma 2.2 that $w \in W_j$ and hence $|W_j| \geq 1$. Applying Lemma 2.6, we have that $|W_j| = 1$ or 2 .

Suppose $|W_j| = 2$. Clearly $u, v, w \in W_j$ and hence $|W_j| \geq 3$. This contradicts Lemma 2.5 which says that E_j consists of a single edge.

Suppose $|W_j| = 1$ (so $W_j = \{w\}$). From Lemma 2.7, it follows that E_j is a star with centre w . But then the existence of the edge $\{u, v\} \in E_j$ yields a contradiction. \square

It may be helpful to summarize the cases enumerated in Theorem 2.8 in more descriptive language. We will say that the j th key graph is of *type* i if $|W_j| = i$. Then Theorem 2.8 can be restated by saying that every key graph is of type 0, 1 or 2. Furthermore, the structure of a key graph of a specified type is as follows:

- type 0** In a key graph (V_j, E_j) of type 0, no vertex in V_j stores the value R_j . Hence, for every vertex $u \in V_j$ and every edge $\{u, v\} \in E_j$ that is incident with u , the vertex u stores the key $L_{u,v}$. There is no restriction on the number of edges in E_j or the structure of E_j .
- type 1** A key graph (V_j, E_j) of type 1 is a star whose centre (say u) stores the value R_j . Any leaf $v \in V_j$ stores the key $L_{u,v}$.
- type 2** A key graph (V_j, E_j) of type 2 consists of a single edge $\{u, v\}$ where u and u both store the value R_j .

Remark 2.2. The IOS considered in Example 2.1 consists of three key graphs of type 1.

2.2 Edge-decompositions into stars

We say that a (secure) G -IOS (f, \mathcal{W}) is a *star-IOS* if every key graph is of type 1. That is, the KPS is based on an edge-decomposition of G into stars. This was the model introduced by Lee and Stinson [7]. In this section, we show that the any secure G -IOS can be transformed into a (secure) G -star-IOS in which the storage of each vertex is the same in the two schemes.

Basically, we need to describe how to change type 0 and 2 key graphs into type 1 key graphs. Let's begin by considering a type 2 key graph, say (V_j, E_j) , which consists of single edge $\{u, v\}$. Both vertices u and v store R_j . If we stipulate that one of vertices u or v stores R_j and the other one stores $L_{u,v}$, then E_j has been transformed to a type 1 key graph with the same storage requirements.

Now we suppose we have a type 0 key graph, (V_j, E_j) . No vertex in V_j stores the value R_j . In this case, we can split this key graph into $|E_j|$ key graphs of type 1, each of which is isomorphic to $K_{1,1}$. Every edge is now assigned a *different* random value by the function f . Furthermore, for every edge $e = \{u, v\} \in E_j$, one endpoint stores the (new) random value $f(e)$ and the other endpoint stores the (new) key $L_{u,v}$.

Summarizing the above discussion, we have the following theorem.

Theorem 2.9. *If (f, \mathcal{W}) is a secure G -IOS, then there exists a secure G -star-KPS in which the storage of every vertex is the same in both schemes.*

3 Optimal storage of IOS

In this section, we focus on secure G -IOS that have minimum possible storage requirements. In view of Theorem 2.9, we can restrict our attention to G -star-IOS. We are interested in the total storage required in such a scheme, as well as the (maximum) storage required by an individual user.

3.1 Total storage

Let $G = (V, E)$ be a graph with $|V| = n$ and $|E| = \epsilon$. Suppose that (f, \mathcal{W}) is a secure G -star-IOS. Then the *storage requirement* of a node u , denoted $s(u)$, is defined to be the number of stars

(i.e., key graphs) that contain u . The *total storage requirement* of the IOS, denoted by $S(f, \mathcal{W})$, is defined as

$$S(f, \mathcal{W}) = \sum_{u \in V} s(u).$$

Let $c(u)$ denote the number of stars for which u is the centre and let $\ell(u)$ denote the number of stars for which u is a leaf. Then

$$s(u) = c(u) + \ell(u) \tag{2}$$

and hence

$$S(f, \mathcal{W}) = \sum_{u \in V} (c(u) + \ell(u)).$$

If we define

$$C = \sum_{u \in V} c(u),$$

then we have that

$$S(f, \mathcal{W}) = C + \sum_{u \in V} \ell(u). \tag{3}$$

Example 3.1. In Example 2.1, we have the following storage requirements:

i	$c(i)$	$\ell(i)$	$s(i)$
1	1	1	2
2	0	3	3
3	1	1	2
4	0	3	3
5	1	0	1

The total storage of the scheme is 11. ■

We now consider each star in the edge-decomposition to be directed as defined in Definition 1.9, i.e., each edge is directed from the leaf to the centre of the star containing it.

Lemma 3.1. $\sum_{u \in V} \ell(u) = \epsilon$.

Proof. It is obvious that $\ell(u) = d^+(u)$ (i.e., the outdegree of u). Clearly $\sum_{u \in V} d^+(u) = \epsilon$, and the result follows. □

It follows from (3.1) and Lemma 3 that

$$S(f, \mathcal{W}) = \epsilon + C. \tag{4}$$

Further, it is easy to see that

$$\begin{aligned} c(u) &= 0 & \text{if } d^-(u) &= 0 \\ c(u) &\geq 1 & \text{if } d^-(u) &> 0. \end{aligned} \tag{5}$$

We are interested in minimizing the total storage, we will denote by $S^*(G)$ the minimum value of $S(f, \mathcal{W})$ over all secure G -star-IOS. In order to compute $S^*(G)$, we need to minimize the value of C in (4). It is convenient to let $C_{\min}(G)$ denote the minimum possible value of C over all edge-decompositions of G into stars.

Lemma 3.2. *Let $\alpha = \alpha(G)$ denote the size of a maximum independent set of vertices in G . Then $C_{\min}(G) = n - \alpha$. Furthermore, $C = C_{\min}(G)$ only if $c(u) \in \{0, 1\}$ for all vertices u .*

Proof. Let V_0 be a set of α independent vertices in V . Direct all edges that are incident with a vertex $v \in V_0$ away from v , and direct any remaining edges arbitrarily. This shows that $C_{\min} \leq n - \alpha$.

Conversely, observe that the set of vertices for which $c(u) = 0$ form an independent set in G . This yields the bound $C_{\min} \geq n - \alpha$. Further, in order for this bound to be met with equality, $c(u) \leq 1$ for all vertices u . \square

Theorem 3.3. *For any graph G , $S^*(G) = n + \epsilon - \alpha$.*

Remark 3.1. For the graph considered in Example 2.1, it is easy to see that $\alpha = 2$. Theorem 3.3 then yields $S^*(G) = 11$. The scheme constructed in Example 2.1 has total storage 11, as noted in Example 3.1. Therefore this scheme has optimal total storage.

We now consider the situation where G is a complete graph K_n . The following result is an immediate corollary of Theorem 3.3; it improves the constructions given in [7, 5] by one.

Corollary 3.4. *$S^*(K_n) = \binom{n+1}{2} - 1$. Further, an edge-decomposition of K_n into stars meets this bound with equality if and only if there is a (necessarily unique) vertex v with $d^-(v) = 0$.*

It is well-known that computing the exact value of $\alpha(G)$ is NP-hard. Thus we also have the following corollary of Theorem 3.3.

Corollary 3.5. *Given a graph G , computing $S^*(G)$ is NP-hard.*

3.2 Maximum storage

It is also of interest to consider the *maximum storage* of a secure G -IOS, say (f, \mathcal{W}) , which is defined to be $S_{\max}(f, \mathcal{W}) = \max\{s(u) : u \in V\}$. Define $S_{\max}^*(G)$ to be the minimum value of $S_{\max}(f, \mathcal{W})$ over all (f, \mathcal{W}) that are secure G -IOS. As before, we can restrict our attention to (f, \mathcal{W}) that are secure G -star-IOS.

We begin with a lemma that states a simplification we can make without loss of generality.

Lemma 3.6. *For any graph G , there exists a secure G -IOS having optimal maximum storage $S_{\max}^*(G)$ in which $c(u) \in \{0, 1\}$ for all vertices u .*

Proof. Consider the star-decomposition associated with a secure G -IOS having optimal maximum storage $S_{\max}^*(G)$. If $c(u) > 1$ for some vertex u , then merge all the stars having centre u . This reduces the storage $s(u)$ and leaves the storage of all other vertices unchanged. Repeat this process until $c(u) \in \{0, 1\}$ for all vertices u . \square

We next give a construction that yields an upper bound on $S^*(G)$. This is a slight modification of a construction given by Lee and Stinson [7] that only applied to regular graphs of even degree.

Theorem 3.7. *Let $G = (V, E)$ be a graph and let d denote the maximum degree of any vertex in V . Then*

$$S_{\max}^*(G) \leq \begin{cases} \frac{d+3}{2} & \text{if } d \text{ is odd,} \\ \frac{d+2}{2} & \text{if } d \text{ is even.} \end{cases}$$

Proof. We first assume that G is connected. Let $V_0 \subseteq V$ be the vertices in V that have odd degree. Clearly $|V_0|$ is even. Let M be any matching of the vertices in V_0 ; M consists of $|V_0|/2$ disjoint edges. Now consider the multigraph $G' = (V, E' = E \cup M)$. Every vertex in G' has even degree, so G' has a (directed) eulerian circuit, say D .

The important property is that, with respect to this orientation defined on the edges in E' , $d^+(u) = d^-(u)$ for every vertex u . Now remove the edges in M and consider the resulting orientation on the edges in E . We have $|d^-(v) - d^+(v)| \leq 1$ if $d(v)$ is odd and $d^-(v) = d^+(v)$ if $d(v)$ is even. This orientation gives rise to an associated decomposition of E into stars, where each star consists of the edges directed into a vertex.

To complete the proof, we observe that any vertex v has storage

$$s(v) = c(v) + \ell(v) = c(v) + d^-(v) \leq 1 + d^-(v).$$

If d is even, then $d^-(v) \leq d/2$ for all v , and if d is odd, then $d^-(v) \leq (d+1)/2$ for all v . The desired result follows.

If G is not connected, then apply the above-described technique to every connected component of G . \square

If we start with a regular graph degree at least two, then we can show that the result obtained above is optimal.

Theorem 3.8. *Let $G = (V, E)$ be a graph that is regular of even degree $d > 0$. Then $S_{\max}^*(G) = (d+2)/2$.*

Proof. We have that $S^*(G) = n + \epsilon - \alpha$. Here $\epsilon = nd/2$ since G is d -regular. Therefore,

$$S_{\max}^*(G) \geq \left\lceil \frac{n + \epsilon - \alpha}{n} \right\rceil = \left\lceil 1 + \frac{d}{2} - \frac{\alpha}{n} \right\rceil.$$

Since $1 \leq \alpha < n$, it follows that $S_{\max}^*(G) \geq 1 + d/2$. We $S_{\max}^*(G) \leq 1 + d/2$ from Theorem 3.7, so the result follows. \square

For regular graphs of odd degree, we have the following similar result.

Theorem 3.9. *Let $G = (V, E)$ be a graph that is regular of odd degree $d \geq 3$. Then $S_{\max}^*(G) = (d+3)/2$.*

Proof. As in the proof of the Theorem 3.8,

$$S^*(G) \geq \left\lceil \frac{n + \epsilon - \alpha}{n} \right\rceil = \left\lceil 1 + \frac{d}{2} - \frac{\alpha}{n} \right\rceil.$$

In any m -regular graph, we have $\alpha \leq n/2$ from Theorem 1.1. Therefore

$$S_{\max}^*(G) \geq \left\lceil 1 + \frac{d}{2} - \frac{n/2}{n} \right\rceil \geq \left\lceil 1 + \frac{d-1}{2} \right\rceil = \frac{d+1}{2}.$$

Now, in order for this bound to be met with equality, it must happen that $C = \alpha = n/2$ and the total storage $S^*(G) = n(d+1)/2$. In this case there will be $n/2$ vertices with $s(v) = 1$ and $n/2$ vertices with $s(v) = d$. So $S_{\max}^*(G) = d$. However, $(d+1)/2 < d$ when $d \geq 3$, so we have a contradiction. Therefore, $S_{\max}^*(G) \geq (d+1)/2 + 1 = (d+3)/2$. $S_{\max}^*(G) \leq (d+3)/2$ from Theorem 3.7, so the result follows. \square

Remark 3.2. A 1-regular graph G is a union of disjoint edges. It is easy to see that $S_{\max}^*(G) = 1$ for such a graph G .

3.3 Minimizing maximum indegree and outdegree

The problem of computing $S_{\max}^*(G)$ is closely related to the *minimum maximum indegree* problem [6, 9], which is defined as follows. Given a graph G , the goal is to direct the edges in G so as to minimize the maximum indegree of a vertex of the resulting directed graph. Suppose we denote this quantity by $\text{MMI}(G)$. It was shown in [9] that $\text{MMI}(G)$ can be computed in polynomial time, more specifically in time $O(\epsilon^2)$, where ϵ is the number of edges in the graph. An improved algorithm can be found in [1]. These algorithms also find an orientation attaining the optimal value $\text{MMI}(G)$.

We will use the following simple result a bit later.

Lemma 3.10. $\text{MMI}(G) \geq \lceil \frac{\epsilon}{n} \rceil$.

Proof. Given any orientation of the edges of a graph G , the *average* indegree is ϵ/n . \square

We can analogously define the *minimum maximum outdegree* problem and the associated quantity $\text{MMO}(G)$ in the obvious way. Observe that $\text{MMO}(G) = \text{MMI}(G)$, simply by reversing the directions of all edges in an optimal solution.

Here is our result linking maximum storage of a G -IOS to $\text{MMO}(G)$.

Theorem 3.11. *For any graph G , we have $\text{MMO}(G) \leq S_{\max}^*(G) \leq \text{MMO}(G) + 1$.*

Proof. Suppose we have with a star-decomposition of G that minimizes $S_{\max}^*(G)$ and suppose that all edges are directed towards the centres of the stars in the decomposition, as usual. From (2), the storage of a vertex u is $s(u) = \ell(u) + c(u)$. The value $\ell(u)$ is clearly equal to the outdegree of u . From Lemma 3.6, we can assume $c(u) = 0$ or 1 . The result follows. \square

We expect for “most” graphs that $S_{\max}^*(G) = \text{MMO}(G) + 1$. The only way it can occur that $\text{MMO}(G) = S_{\max}^*(G)$ is if every vertex whose outdegree is equal to $\text{MMO}(G)$ has indegree equal to 0. Nevertheless, this can occur: we show that there are infinitely many graphs for which $\text{MMO}(G) = S_{\max}^*(G)$.

Theorem 3.12. *For any integer $n > 15$, there exists a graph G having n vertices such that $\text{MMO}(G) = S_{\max}^*(G)$.*

Proof. For any integer $t > 10$, let $G = K_5 \vee \overline{K_t}$ (i.e., G is the join of K_5 and a set of t independent vertices; see Definition 1.12). This graph has $n = t + 5$ vertices and $\epsilon = 5t + 10$ edges. From Lemma 3.10, since $t > 10$, we see that $\text{MMO}(G) \geq 5$. We can construct an orientation of the edges of G in which the t vertices in the $\overline{K_t}$ each have outdegree 5 and indegree 0, and the vertices in the K_5 each have outdegree 2 and indegree $t + 2$. This shows that $\text{MMO}(G) \leq 5$, whence $\text{MMO}(G) = 5$. Since the vertices of outdegree 5 all have indegree equal to 0, the resulting star decomposition proves that $S_{\max}^*(G) = \text{MMO}(G) = 5$. \square

Since $\text{MMO}(G)$ can be computed in polynomial time, Theorem 3.11 establishes that we can compute an integer T such that value $S_{\max}^*(G) = T$ or $T + 1$, in polynomial time. In fact, as we now show, it is possible to compute the exact value of $S_{\max}^*(G)$ in polynomial time.

Theorem 3.13. *Let $G = (V, E)$ be a graph and let*

$$W = \{v \in V : \deg(v) > \text{MMO}(G)\}.$$

Let $H = (W, F)$ be the subgraph of G induced by W . Then $\text{MMO}(G) = S_{\max}^(G)$ if and only if $\text{MMO}(H) < \text{MMO}(G)$.*

Figure 1: An algorithm to compute $S_{\max}^*(G)$

1. Compute $\text{MMO}(G)$.
2. Construct the graph H .
3. Compute $\text{MMO}(H)$.
4. If $\text{MMO}(H) < \text{MMO}(G)$ then $S_{\max}^*(G) = \text{MMO}(G)$ else $S_{\max}^*(G) = \text{MMO}(G) + 1$.

Proof. Suppose $\text{MMO}(G) = S_{\max}^*(G)$ and consider an orientation of the edges in E so that the maximum outdegree of any vertex is $\text{MMO}(G)$. Let $w \in W$; then w has indegree greater than 0. It follows that $s(w) = 1 + \ell(w)$, where $\ell(w)$ equals the outdegree of w . Therefore

$$\ell(w) < s(w) \leq S_{\max}^*(G) = \text{MMO}(G).$$

Since this holds for every vertex $w \in W$, we have $\text{MMO}(H) < \text{MMO}(G)$.

Conversely, suppose that $\text{MMO}(H) < \text{MMO}(G)$. Consider an orientation of the edges in F so that the maximum outdegree of any vertex in W is at most $\text{MMO}(H)$. Next, direct any edges having one endpoint in W towards the incident vertex in W . At this point, we have

$$s(w) \leq 1 + \ell(w) \leq 1 + \text{MMO}(H) \leq \text{MMO}(G)$$

for every vertex $w \in W$. Finally, direct any edges with both endpoints in $V \setminus W$ arbitrarily. Then, for any vertex $v \in V \setminus W$, we have

$$s(v) \leq \deg(v) \leq \text{MMO}(G).$$

Thus $\text{MMO}(G) = S_{\max}^*(G)$. □

Example 3.2. Let us return again to the graph G considered in Example 2.1. It is easy to see that $\text{MMO}(G) = 2$. Further, $H = G$ and hence $S_{\max}^*(G) = 3$. Thus the scheme constructed in Example 2.1 has optimal maximum storage.

Example 3.3. In the construction given in the proof of Theorem 3.12, we see that H consists of the five vertices in the K_5 and hence $\text{MMO}(H) = 2$.

As an immediate corollary of Theorem 3.13, we obtain a polynomial-time algorithm to compute $S_{\max}^*(G)$. This algorithm is presented in Figure 1.

Remark 3.3. Using ideas from the proof of Theorem 3.13, the above algorithm can be modified in a straightforward way to construct a scheme attaining the value $S_{\max}^*(G)$.

4 Discussion and Summary

We have studied a general type of key redistribution scheme based on hashing secret values along with users' IDs. We gave necessary and sufficient conditions for schemes of this type to be secure, and we studied the problem of minimizing users' storage in these schemes.

Choi, Acharya and Gouda [5] also studied key predistribution in a similar setting. They only considered the situation where the communication graph is a complete graph and they gave a construction that is basically equivalent to the one found in [7]. They also considered lower bounds on the total storage of schemes of this type. Their model is very similar to ours, but they do not assume (as we did) that the key derivation function is a random oracle. In [5, Theorem 6], it is stated that the total storage required by a secure scheme is at least $n(n-1)/2$. The proof involves analyzing the implications of an equation of the form

$$F(iv, ku) = F(iu, kv), \tag{6}$$

where F is a public key derivation function, iu and iv are public values, and ku and kv are secret values known to nodes u and v respectively.

The equation (6) ensures that nodes u and v will compute the same pairwise key. Moreover, it is assumed ku and kv are each used for the computation of at least one other key, and then a contradiction is derived. It is observed in [7] that, under these circumstances, it should be infeasible to compute ku given iv and $F(iu, kv)$, and it should also be infeasible to compute kv given iu and $F(iv, ku)$. It is then claimed that this means that values ku and kv satisfying (6) cannot be computed when the scheme is set up. However, this last assertion does not seem to consider the possibility that the entity that sets up the scheme can compute these values, even though the nodes u and v might not be able to compute kv or ku , respectively.

The Blom scheme [3] illustrates how this can happen. For simplicity, we consider a Blom scheme secure against individual nodes. Such a scheme is constructed by a trusted authority (TA) first choosing a symmetric polynomial of the form $g(x_1, x_2) = a + b(x_1 + x_2) + cx_1x_2$. A node u is given the polynomial $f_u(z) = g(iu, z)$ and v is given the polynomial $f_v(z) = g(iv, z)$. The pairwise key for nodes u and v is $g(iu, iv) = g(iv, iu)$. Node u computes this key as $f_u(iv)$ and node v computes $f_v(iu)$. Note that node u cannot compute f_v and node v cannot compute f_u , but the TA who sets up the scheme knows the relationship between these polynomials.

In the setting we studied, where the key derivation function is a random oracle, the equation (6) will not hold, so the above discussion does not apply. We were therefore able to prove stronger lower bounds on the total storage, as we presented in Section 3.
