Abstract

There is mixed evidence about the predictive validity of the Griffiths mental developmental scales. This study aimed to assess the predictive value of developmental assessments of children in their second year using the Griffiths mental development scales for neuro-developmental status at five years using the Wechsler preschool and primary scale of intelligence, revised (WPPSI-R). In a longitudinal study 253 children were assessed in their second year of life using the Griffiths scales and again at five years using the WPPSI-R. The scores were compared and the predictability of the WPPSI-R outcome on the basis of Griffiths scores was assessed. The WPPSI-R full scale IQ and the performance IQ at age five could be predicted moderately by the Griffiths general quotient (GQ) and by the personal/social scale. The Griffiths GQ was not a significant predictor of verbal IQ at age 5. The Griffiths performance scale predicted subsequent WPPSI-R performance IQ, and marginally the Full Scale IQ. For the early identification of children at risk for language delay, the Griffiths scales may not be suitable. However, a shortened form would be useful to predict overall cognitive development from the second year to school entry, focussing on the personal-social and performance scales.

Introduction

It has been known for some time that although the commonly used developmental scales for infants (Bayley mental developmental scales1 and the Griffiths scales2) have some ability to predict skills at a later age, they are not as sensitive as developmental assessments used when children are 5 years or above. This is mainly because of the lack of verbal skills range possessed by toddlers compared to older children, which limits the comparability of the tasks in assessments at the two ages.

Little research has been done to show the predictability of either of the developmental systems. Studies previously done tended to use small numbers of children,3 use children who have specific characteristics such as being very premature or having conditions that may affect their development in an unrecognised manner and which could skew the results of the predictability.4

Some previous studies compared Bayley scales of infant development scores and subsequent WPPSI-R scores. A search of the medical literature revealed only one study, performed in 1977, which compared the Bayley and the Griffiths scales. The sample was small (50) and the infants were from a neonatal follow-up clinic and therefore high-risk for delay in cognitive development. Nevertheless, the potential of the Griffiths scale was suggested by the strong association found between the Griffiths and the Bayley tests.5

This study, designed to investigate the development over time of children conceived by assisted reproductive technology (ART)6 is also one of the largest to be able to investigate the predictability of neuro-developmental scores in the second year for development in the fifth year of life. The longitudinal study used the Griffiths mental development scales to assess a cohort of children at a mean age of 17 months. These children were reassessed at 54 months of age.7 The Griffiths mental development scales have been examined to establish the extent to which they accurately predict children’s neuro-developmental progress at 54 months of age using the Wechsler preschool and primary scale of intelligence, Revised (WPPSI-RUK).8

The children were either naturally conceived, or from intracytoplasmic sperm injection (ICSI), a type of in vitro fertilisation, but for the purposes of this paper nature of conception is not considered. This report describes the extent to which the earlier cognitive measure can predict subsequent development.

Materials and Methods

Procedure

At the original assessment8 and at follow-up,9 the children were assessed by a single researcher. In their second year (mean age 17.3 months) all children were assessed by a paediatrician. At the second evaluation (mean age 5.0 years) a trained psychologist assessed the children, unaware of their mode of conception and blind to previous test scores. The first language of all of the children was English. They were Caucasian, born at term, singleton and with normal birth-weight. Measurements at the two time points were available for 253 children: 165 ICSI conceived children (65.2%) and 88 naturally conceived children (34.7%). The sex distribution between the two groups was similar (female 113, male 140). Further details of the original cohort10 and the follow-up group11 have been previously described.

Measures

The Griffiths mental development scales11 uses a simple ratio transformation, dividing the mental age by chronological age yielding slightly different means and standard deviations for the total index and the scale scores. It yields a general cognitive quotient (GQ, mean 100.2, s.d. 12.8) and at the 1-2 year age has 5 sub-scales: hearing and speech (mean 99.8, s.d. 17.8); hand and eye coordination (mean 100.5, s.d. 15.6); personal-social development (mean 100.3, s.d. 16.2); locomotor development (mean 100.4, s.d. 16.3); performance (5 tests) and both verbal and performance (5 tests) and both verbal and performance IQ scores (mean 100, s.d. 10).

Analysis

Linear regressions were calculated predict-
ing the WPPSI-R verbal IQ, performance IQ and full scale IQ scores from Griffiths GQ scores and to indicate the variance in WPPSI-R IQ explained by the Griffiths GQ. The predictive power of each Griffiths scale was examined using ANOVA.

Results

The mean Griffiths GQ score (98.39) and mean WPPSI-R scores (FSIQ, 106.01; VIQ 101.03; PIQ 111.21) were in the average range.

Prediction of WPPSI-R IQ scores from Griffiths general quotient

The Griffiths GQ scores had a weak but statistically significant power to predict subsequent WPPSI-R full-scale IQ and performance IQ (Table 1; Figures 1 and 2). The predictive power of the Griffiths GQ for the WPPSI-R verbal IQ was minimal and not significant (Table 1, Figure 3).

Discussion

When trying to predict the subsequent WPPSI-R scores at age 5, the Griffiths scale, completed during toddlerhood at an age when language was only just emerging (17 months), has a significant predictive power for performance IQ and full scale IQs but not the verbal IQ. This suggests that there is less predictive power for this age group in the Griffiths items from the hearing and speech scale that revolve around language-based tasks that are similar to the WPPSI-R verbal IQ score. Those items in the personal/social scale for the second year reflect some verbal skills such as communicating about experiences and these may be more useful than items indicating the extent of vocabulary, which can vary widely during the second year. The Griffiths measure is therefore more likely to be useful as a general indicator of subsequent development, but may not be the most appropriate test if language development is a particular target, for instance of an early intervention or to identify children who may in the future have language delay. It may be more useful for research purposes when mean values for groups are the focus rather than for clinical work focussing on specific children to identify those potentially in need of intervention.
