## **Abstract**

This paper examines for the first time the impact of problem loans on productivity growth. We exploit a new data set of problem loans, identified as bankrupt and restructured loans, particularly available for Japanese commercial banks. Our parametric methodology quantifies the impact of these loans on productivity growth of the Japanese banking system, which endured a long-lasting effect of the crisis in the early 1990s. The results reveal that Japanese bank productivity growth was severely constrained by bankrupt loans. Further, we perform convergence analysis to examine convergence across regions and over time. Limited convergence is observed, though Regional Banks seem to form convergence clusters for some regions which are illustrated by the blue and green areas in our map of Japan.

Keywords: Bank productivity; Convergence; Bankrupt loans; Restructured loans; Japan.

JEL classification: D24, G21, C33

## **1. Introduction**

There has been extensive theoretical and empirical research into the field of firm efficiency and productivity (Heshmati et al., 2014; Kumbhakar and Tsionas, 2016; Sun et al., 2015). In terms of bank efficiency and productivity, the outbreak of the global financial crisis has driven a surge of banking studies (Matousek et al., 2015; Tsionas et al., 2015), unfolding the paramount importance of financial intermediaries within the economic system. In terms of productivity growth, evidence is rather limited with studies that apply parametric methods to evaluate bank productivity (Boucinha et al., 2013; Feng and Serletis, 2010; Feng and Zhang, 2012, 2014). As indicated in a review of non-parametric productivity applied in banking by Fethi and Pasiouras (2010), the majority of studies adopt a non-parametric approach (Fukuyama and Weber, 2005, 2010; Liu and Tone, 2008).

Our study extends the literature on bank productivity by opting for a parametric estimation technique. We decompose bank productivity growth into different components, namely the effects of problem loans, which are essentially uncontrollable inputs, quasi-fixed input, returns to scale, and technological change. The Japanese banking system is of interest as its performance has been undermined by an unprecedented volume of bankrupt and restructured loans. These loans are referred as risk-monitored loans disclosed in accordance with the Japanese Banking Law. Moreover, in Japanese banking literature, bank efficiency studies have dominated the research field of bank performance, for example Drake and Hall (2003), Fukuyama and Weber (2005), Fukuyama and Weber (2010), Barros et al. (2012), Yang and Morita (2013). Japanese bank productivity has been rather neglected (Assaf et al., 2011; Fukuyama, 1995; Fukuyama et al., 1999).

We, thus, fill a gap in the literature and apply for the first time a productivity growth decomposition to Japanese banks, where problem loans' impact would be revealed.<sup>1</sup> Previous literature has considered nonperforming loans as uncontrollable inputs or undesirable outputs in the banking production process (Assaf et al., 2013; Barros et al., 2012; Drake and Hall, 2003; Fukuyama and Weber, 2008; Glass et al., 2014; Hughes and Mester, 2010; Mamatzakis et al., 2015). We follow Drake and Hall (2003) and Hughes and Mester (2010) to treat bankrupt and restructured loans as uncontrollable inputs in our productivity decomposition.<sup>2</sup> Given the extensive volume of bankrupt and restructured loans in Japan, we expect that they have an impact on bank productivity. Arguably, banks may receive payments of the principal and interest on these loans subject to borrowers' financial health. These overdue loans in turn would raise bank's operating costs in the short-run. Hence, one would expect these loans to deteriorate bank productivity.

Alongside bankrupt and restructured loans, we also employ equity as a quasi-fixed input (Berger and DeYoung, 1997; Hughes et al., 2001; Ray and Das, 2010). Within a short period, it would be unfeasible to adjust the level of equity considerably and quickly (Lozano-Vivas and Pasiouras, 2014). In the event of unexpected losses, the level of equity is of utmost importance to ensure bank safety and soundness, preventing banks from temporary illiquidity and insolvency (Diamond and Rajan, 2000). Equity would also serve as a cost-reducing factor

---

<sup>1</sup> The decomposition is similar to decomposing productivity growth with respect to public infrastructure in agriculture (Mamatzakis, 2003; Morrison and Schwartz, 1996) or branch growth in banking (Kim and Weiss, 1989).

<sup>2</sup> Using information on nonperforming loans, Drake and Hall (2003) argue that reducing these loans, to some extent, is not under bank managers' control, but the financial ability of borrowers and their willingness of repayment. Nonperforming loans have been mentioned in Hughes and Mester (2010) as a proxy for quasi-fixed input, but they do not provide empirical results.

due to less interest paid for debt financing (Hughes and Mester, 2013). Finally, the inclusion of equity in our productivity decomposition is of importance for Japan. The reason is that during the banking crisis in the late 1990s, there was a prolonged period of undercapitalisation until the early 2000s. The Japanese authorities responded by injecting public capital four times between March 1998 and June 2003 (Hoshi and Kashyap, 2010), hoping to stabilise the financial market and revive the banking industry.

The contribution of this study can be summarised in the following ways. First, we expand the parametric methodological literature of bank productivity growth (Boucinha et al., 2013; Casu et al., 2013; Lozano-Vivas and Pasiouras, 2014) as opposed to the broadly applied nonparametric one (Alam, 2001; Berg et al., 1992; Delis et al., 2011; Fiordelisi and Molyneux, 2010; Grifell-Tatjé and Lovell, 1997; Kao and Liu, 2014; Wheelock and Wilson, 1999). Our paper refers to Japan, which serves as an excellent case study given the trouble of its banking industry (Barros et al., 2009; Fukuyama, 1995; Fukuyama and Weber, 2002). Second, we exploit a new data set of bankrupt and restructured loans, which are disaggregated from “risk-monitored loans” disclosed subject to the Japanese Banking Law. The adopted approach enables a comprehensive analysis by allowing for the impact of these loans on total factor productivity growth. Finally, we test for convergence – catching up effect – among Japanese banks and geographic regions by using club convergence analysis proposed by Phillips and Sul (2007).

Our results show that productivity growth in Japanese commercial banks is impaired by the impact of bankrupt loans. The destructive effect of these loans varies over time, appearing to capture events such as government interventions, the global financial crisis, and the Tohoku tsunami/earthquake. Interestingly, restructured loans are among the drivers of productivity growth, as they are found to lower costs. With regard to the club convergence analysis, we find divergence in productivity growth across regions over time. However, some integration, and

thus convergence, is identified for Regional Banks I, whereas there exists some clubs of convergence within City Banks, and within the regions of Hokkaido, Tohoku, Kanto, Chubu, Chugoku, and Shikoku.

The remainder of this paper is structured as follows. Section 2 provides an overview of the literature in bank productivity. Section 3 presents the methodology, followed by the data description in section 4. Empirical results are provided in section 5, and convergence tests are discussed in section 6. Finally, section 7 concludes.

## **2. Literature review**

This section highlights the literature in bank productivity with a particular focus on the approaches used to decompose total factor productivity (TFP) growth. In what follows, we briefly survey the studies that apply nonparametric and parametric methodologies to measure bank productivity.

### *2.1. Non-parametric studies*

The decomposition of the Malmquist productivity index through Data Envelopment Analysis (DEA) has prevailed in the banking literature. As indicated in a comprehensive review for bank efficiency and productivity (Fethi and Pasiouras, 2010), almost all studies before 2010 apply this approach. Berg et al. (1992) use this technique to obtain the productivity index for Norwegian banking, where the largest banks are found to be strongly productive after deregulation. Wheelock and Wilson (1999) and Alam (2001) show that the driving factor for productivity growth in US banking was advances in technology during 1980s-1990s. Grifell-Tatjé and Lovell (1997) replace the Malmquist productivity index by a generalised Malmquist productivity index, allowing for the measurement of the contribution of scale economies on productivity growth. In a similar vein, Fiordelisi and Molyneux (2010) obtain TFP growth of

European banking, where technological change was the most productive component which contributed to shareholder's value. Other studies include Tortosa-Ausina et al. (2008), which use a bootstrapping techniques to derive the Malmquist index, and Kao and Liu (2014), which employ a probabilistic analysis. Productivity growth studies in Japanese banking are also dominated by those adopting nonparametric methodologies (Assaf et al., 2011; Barros et al., 2009; Fukuyama, 1995; Fukuyama et al., 1999; Fukuyama and Weber, 2002).

Flexibility is the main feature of a semi-parametric approach that attracts research interest. This methodology to measure productivity, however, has been mainly applied in nonbanking research (Heshmati et al., 2014). Sun et al. (2015) propose a semiparametric cost frontier of which the slope coefficients are a nonparametric function of the time trend. The semiparametric cost function is estimated first, followed by a decomposition of inefficiency into time-varying and time-invariant components. Finally, productivity is decomposed based on the estimated cost frontier. Although the authors use Norwegian farming data set as an example, this methodology could also be of interest for banking applications.

## *2.2. Parametric studies*

Bank productivity in parametric studies is mainly derived from estimating cost, profit, or distance functions. Berger and Mester (2003) estimate cost and profit functions for US banks during 1991-1997 to obtain cost productivity change and profit productivity change. Productivity change in this study is defined as changes in best practice and changes in inefficiency. Focusing on off-balance sheet variables, Lozano-Vivas and Pasiouras (2014) also obtain productivity change by applying this parametric decomposition on an international sample for the period 1999-2006. Estimating a cost function, Boucinha et al. (2013) obtain the estimated parameters and compute total factor productivity change for Portuguese banks. Their

results suggest that technological progress was the main driver of total factor productivity change from 1992 to 2006.

Chaffai et al. (2001) use a stochastic output distance function to decompose the Malmquist index into pure technological effect and environmental effect. Koutsomanoli-Filippaki et al. (2009) parameterise the directional distance function to examine Luenberger productivity indicator for banking industries in Central and Eastern European countries (1998-2003). Their finding suggests that the dominant factor driving productivity growth was technological change. Feng and Zhang (2012) and Feng and Zhang (2014) adopt a true random stochastic distance frontier model to allow for unobserved heterogeneity among US banks. The “output-distance-function-based-Divisa” productivity index proposed in Feng and Serletis (2010) is used in these studies to measure TFP growth of large US banks.

### 3. Methodology

#### 3.1. Decomposing productivity growth

The starting point is to minimise total cost given a production function  $F$ . This optimisation is:

$$C(w, Y, b, E, t) = \min_X \left\{ \sum wX : F(X, Y, b, E, t) = 0 \right\} \quad (1)$$

$$\text{or } C \equiv \sum_{k=1}^K w_k X_k \quad (2)$$

where  $F$  denotes the production function with output quantity  $Y$ , input quantity  $X$ , input prices  $w$  (with  $k$  being the number of input prices), uncontrollable input  $b$ , equity  $E$ , and technology  $t$ . We treat equity  $E$  as quasi-fixed as it is difficult to adjust the quantity of equity quickly in the short-run (Lozano-Vivas and Pasiouras, 2014). To derive the impact of uncontrollable inputs on productivity growth, we adopt the methodology proposed by Morrison and Schwartz (1996).

The total differentiation of equation (1) with respect to time yields:

$$\frac{dC}{dt} = \sum_{k=1}^K \frac{\partial C}{\partial w_k} \frac{\partial w_k}{\partial t} + \sum_{m=1}^M \frac{\partial C}{\partial Y_m} \frac{\partial Y_m}{\partial t} + \sum_{j=1}^J \frac{\partial C}{\partial b_j} \frac{\partial b_j}{\partial t} + \frac{\partial C}{\partial E} \frac{\partial E}{\partial t} + \frac{\partial C}{\partial t} \quad (3)$$

Dividing both sides of equation (3) by total cost  $C$ , multiplying and dividing the terms in the right hand side of equation (3) (except the last term) with input prices, outputs, uncontrollable inputs, and equity respectively, we obtain:

$$\frac{\dot{C}}{C} = \sum_{k=1}^K \frac{\partial C}{C} \frac{w_k}{\partial w_k} \frac{\dot{w}_k}{w_k} + \sum_{m=1}^M \frac{\partial C}{C} \frac{Y_m}{\partial Y_m} \frac{\dot{Y}_m}{Y_m} + \sum_{j=1}^J \frac{\partial C}{C} \frac{b_j}{\partial b_j} \frac{\dot{b}_j}{b_j} + \frac{\partial C}{C} \frac{E}{\partial E} \frac{\dot{E}}{E} + \frac{1}{C} \frac{\partial C}{\partial t} \quad (4)$$

with a dot above variables denoting derivative with respect to time <sup>3</sup> ;

$$S_k = \frac{\partial C}{C} \frac{w_k}{\partial w_k} \equiv \frac{w_k X_k}{C}, k = 1, \dots, K \text{ being the cost share of input } k; \quad \varepsilon_{CY_m} = \frac{\partial C}{C} \frac{Y_m}{\partial Y_m}, m = 1, \dots, M \text{ being}$$

the cost elasticity with respect to output  $m$ ;  $\varepsilon_{Cb_j} = \frac{\partial C}{C} \frac{b_j}{\partial b_j}, j = 1, \dots, J$  being the cost elasticity with

respect to uncontrollable input  $j$ ;  $\varepsilon_{CE} = \frac{\partial C}{C} \frac{E}{\partial E}$  being the cost elasticity with respect to equity;

and  $\varepsilon_{Ct} = \frac{1}{C} \frac{\partial C}{\partial t}$  being the technical change.

Thus, we can obtain equation (5):

$$\frac{\dot{C}}{C} = \sum_{k=1}^K S_k \frac{\dot{w}_k}{w_k} + \sum_{m=1}^M \varepsilon_{CY_m} \frac{\dot{Y}_m}{Y_m} + \sum_{j=1}^J \varepsilon_{Cb_j} \frac{\dot{b}_j}{b_j} + \varepsilon_{CE} \frac{\dot{E}}{E} + \varepsilon_{Ct} \quad (5)$$

Rearranging equation (5) with respect to  $\varepsilon_{Ct}$ , we get:

$$\varepsilon_{Ct} = \frac{\dot{C}}{C} - \sum_{k=1}^K S_k \frac{\dot{w}_k}{w_k} - \sum_{m=1}^M \varepsilon_{CY_m} \frac{\dot{Y}_m}{Y_m} - \sum_{j=1}^J \varepsilon_{Cb_j} \frac{\dot{b}_j}{b_j} - \varepsilon_{CE} \frac{\dot{E}}{E} \quad (6)$$

---

<sup>3</sup>  $w_k = \partial w_k / \partial t$ ;  $Y_m = \partial Y_m / \partial t$ ;  $b_j = \partial b_j / \partial t$ ;  $E = \partial E / \partial t$ . Our data consist of  $k = 2$  input prices,  $m = 2$  outputs,  $j = 2$  uncontrollable inputs (bankrupt and restructured loans).

From equation (6), we can obtain equation (11) by totally differentiating equation (2) with respect to time and with some arrangements detailed as below:

The total differentiation of equation (2) with respect to time is:

$$\frac{dC}{dt} = \sum_{k=1}^K X_k \frac{\partial w_k}{\partial t} + \sum_{k=1}^K w_k \frac{\partial X_k}{\partial t} \quad (7)$$

Dividing both sides of equation (7) by total cost, we get:

$$\frac{\dot{C}}{C} = \sum_{k=1}^K \frac{X_k}{C} \dot{w}_k + \sum_{k=1}^K \frac{w_k}{C} \dot{X}_k \quad (8)$$

For the right-hand side of equation (8), multiplying and dividing the first term and second term with  $w_k$  and  $X_k$  respectively, we get:

$$\frac{\dot{C}}{C} = \sum_{k=1}^K \frac{w_k X_k}{C} \frac{\dot{w}_k}{w_k} + \sum_{k=1}^K \frac{w_k X_k}{C} \frac{\dot{X}_k}{X_k} \quad (9)$$

As  $S_k = w_k X_k / C$ , rearranging (9), we obtain:

$$\sum_{k=1}^K \frac{w_k X_k}{C} \frac{\dot{X}_k}{X_k} = \frac{\dot{C}}{C} - \sum_{k=1}^K S_k \frac{\dot{w}_k}{w_k} \quad (10)$$

Thus, substituting the first two terms in the right-hand side of equation (6) by the left-hand side of equation (10), we obtain equation (11):

$$\varepsilon_{Ct} = \sum_{k=1}^K \frac{w_k X_k}{C} \frac{\dot{X}_k}{X_k} - \sum_{m=1}^M \varepsilon_{CY_m} \frac{\dot{Y}_m}{Y_m} - \sum_{j=1}^J \varepsilon_{Cb_j} \frac{\dot{b}_j}{b_j} - \varepsilon_{CE} \frac{\dot{E}}{E} \quad (11)$$

The total factor productivity growth (if constant returns to scale,  $\varepsilon_{C_Y} = 1$ ), the Solow residual, showing the difference between the rate of change of outputs and the rate of change of inputs is:

$$TFP = \sum_{m=1}^M \frac{\dot{Y}_m}{Y_m} - \sum_{k=1}^K \frac{w_k X_k}{C} \frac{\dot{X}_k}{X_k} \quad (12)$$

In the case of nonconstant returns to scale, the traditional measure of productivity growth needs to be adjusted. Combining equations (11) and (12), we get:

$$\varepsilon_{Ct} = \sum_{m=1}^M \frac{\dot{Y}_m}{Y_m} - TFP - \sum_{m=1}^M \varepsilon_{CY_m} \frac{\dot{Y}_m}{Y_m} - \sum_{j=1}^J \varepsilon_{Cb_j} \frac{\dot{b}_j}{b_j} - \varepsilon_{CE} \frac{\dot{E}}{E} \quad (13)$$

Rearranging equation (13), we obtain equation (14):

$$TFP = -\varepsilon_{Ct} + \left( \sum_{m=1}^M \frac{\dot{Y}_m}{Y_m} - \sum_{m=1}^M \varepsilon_{CY_m} \frac{\dot{Y}_m}{Y_m} \right) - \sum_{j=1}^J \varepsilon_{Cb_j} \frac{\dot{b}_j}{b_j} - \varepsilon_{CE} \frac{\dot{E}}{E} \quad (14)$$

The terms in the right-hand side of equation (14) are the impact of technological change, the scale effect  $\left( \sum_{m=1}^M \frac{\dot{Y}_m}{Y_m} - \sum_{m=1}^M \varepsilon_{CY_m} \frac{\dot{Y}_m}{Y_m} \right)$ , the impact of uncontrollable inputs (bankrupt and restructured loans), and the impact of equity respectively.

### 3.2. The translog function

The specification of our translog cost function is as follows<sup>4</sup>:

$$\begin{aligned} \ln C = & \alpha_0 + \sum_{k=1}^K \alpha_k \ln w_k + \sum_{m=1}^M \beta_m \ln Y_m + \sum_{j=1}^J \phi_j \ln b_j + \lambda \ln E + \frac{1}{2} \sum_{k=1}^K \sum_{l=1}^L \alpha_{kl} \ln w_k \ln w_l \\ & + \frac{1}{2} \sum_{m=1}^M \sum_{n=1}^N \beta_{mn} \ln Y_m \ln Y_n + \frac{1}{2} \sum_{j=1}^J \sum_{s=1}^S \phi_{js} \ln b_j \ln b_s + \frac{1}{2} \lambda_e \ln E \ln E \\ & + \sum_{k=1}^K \sum_{m=1}^M \delta_{km} \ln w_k \ln Y_m + \sum_{k=1}^K \sum_{j=1}^J \gamma_{kj} \ln w_k \ln b_j + \sum_{k=1}^K \mu_k \ln w_k \ln E + \sum_{m=1}^M \sum_{j=1}^J \varphi_{mj} \ln Y_m \ln b_j \\ & + \sum_{m=1}^M \sigma_m \ln Y_m \ln E + \sum_{j=1}^J \varsigma_j \ln b_j \ln E + \theta_t t + \frac{1}{2} \theta_{tt} t^2 + \sum_{k=1}^K \alpha_{kt} \ln w_k t + \sum_{m=1}^M \beta_{mt} \ln Y_m t \\ & + \sum_{j=1}^J \phi_{jt} \ln b_j t + \lambda_t \ln E t + \varepsilon \end{aligned} \quad (15)$$

<sup>4</sup> Subscripts  $i$  for banks ( $i=1, \dots, N$ ) and  $t$  for time ( $t=1, \dots, N$ ) are omitted for simplification.

where  $w_k$ ,  $Y_m$ ,  $b_j$ ,  $E$  denote  $k$ th input price,  $m$ th output,  $j$ th uncontrollable input, and equity respectively.

Applying Shephard's lemma for equation (15), we obtain the shares of cost attributed to input price  $k$ th:

$$S_{w_k} = \alpha_k + \alpha_{kk} \ln w_k + \sum_{l=1}^L \alpha_{kl} \ln w_l + \sum_{m=1}^M \delta_{km} \ln Y_m + \sum_{j=1}^J \gamma_{kj} \ln b_j + \mu_k \ln E + \alpha_{kt} t \quad (16)$$

Total differentiating equation (15) with respect to output  $m$ th, uncontrollable input  $j$ th, and equity, we obtain:

$$\varepsilon_{CY_m} = \beta_m + \beta_{mm} \ln Y_m + \sum_{n=1}^N \beta_{mn} \ln Y_n + \sum_{k=1}^K \delta_{km} \ln w_k + \sum_{j=1}^J \varphi_{mj} \ln b_j + o_m \ln E + \beta_{mt} t \quad (17)$$

$$\varepsilon_{Cb_j} = \phi_j + \phi_{jj} \ln b_j + \sum_{s=1}^S \phi_{js} \ln b_s + \sum_{k=1}^K \gamma_{kj} \ln w_k + \sum_{m=1}^M \varphi_{mj} \ln Y_m + \varsigma_j \ln E + \phi_j t \quad (18)$$

$$\varepsilon_{CE} = \lambda + \lambda_e \ln E + \sum_{k=1}^K \mu_k \ln w_k + \sum_{m=1}^M o_m \ln Y_m + \sum_{j=1}^J \varsigma_j \ln b_j + \lambda_t t \quad (19)$$

The cost function requires a monotonic condition of non-decreasing in  $w$ . We impose the usual symmetry restrictions  $\alpha_{kl} = \alpha_{lk}$ ,  $\beta_{mn} = \beta_{nm}$ ,  $\phi_{js} = \phi_{sj}$  and linear homogeneity restriction on the cost function (15) with respect to input prices:

$$\sum_{k=1}^K \alpha_k = 1; \sum_{k=1}^K \alpha_{kl} = 0 \quad \forall l; \sum_{k=1}^K \delta_{km} = 0 \quad \forall m; \sum_{k=1}^K \gamma_{kj} = 0 \quad \forall j; \sum_{k=1}^K \mu_k = 0; \sum_{k=1}^K \alpha_{kt} = 0 \quad (20)$$

There are two input prices: price of fund, and price of physical capital and labour.<sup>5</sup> We estimate equation (15) by using the price of fund to normalise. The results obtained are then used to compute the impact of each component on productivity growth.

---

<sup>5</sup> Please refer to Data section.

#### 4. Data

This paper employs a new data set of problem loans in Japan, providing new information of a critical bank uncontrollable input. Moreover, we disaggregate problem loans disclosed in accordance with the Japanese Banking Law into two categories. The first one consists of loans to borrowers in legal bankruptcy, and past due loans in arrears by six months or more. The second component comprises loans in arrears by 3 months or more but less than 6 months, and restructured loans. For simplicity, we name these two types of problem loans as bankrupt loans (*BRL*) and restructured loans (*RSL*) thereafter. Such disaggregation of problem loans has not been employed widely in the Japanese banking productivity literature (Mamatzakis et al., 2015). This disaggregation allows us to explore the extent to which each uncontrollable input, namely bankrupt loans and restructured loans, affects bank productivity.

In the aftermath of the asset price bubble that burst late 1990s in Japan, problem loans rose dramatically since a vast number of firms went bankrupt or experienced business difficulties. The cost of bankrupt and restructured loans in 1997 was 30 trillion JPY (Hoshi and Kashyap, 2000). However, some estimate the actual value in excess of 100 trillion JPY (Hoshino, 2002). After 1998, the government encouraged banks to increase their lending to small- and medium-sized firms (SMEs) in order to ease the “credit crunch” (Hoshi, 2011; Hoshi and Kashyap, 2010). However, the fact that the government subsidised these unprofitable borrowers dampened the entry and investment of productive firms, leading to fewer good lending opportunities for solvent banks (Caballero et al., 2006). Prior to 2002, the government had deployed rescue schemes by injecting capital and bailing out troubled banks, but it had been claimed that there were delays of much-needed restructuring at the banking industry (Caballero et al., 2006). Furthermore, misdirected bank lending augmented the accumulated level of bankrupt and restructured loans. In 2002, the level of these loans fell, reflecting the effort of banks to reduce problem loans under the reform program introduced by Heizo Takenaka, who

was in charge of the Financial Services Agency. After the recovering period, the global financial crisis 2007-2008 somewhat increased further the level of bankrupt and restructured loans.

We employ a unique semi-annual data set provided by the Japanese Bankers Association. Our panel data consist of 3484 observations for Japanese commercial banks - 10 City Banks, 65 Regional Banks I, and 56 Regional Banks II - from financial years 2000 to 2014. City Banks are the largest banks amongst the three types. Apart from conventional banking activities, their operation spreads widely from security investment to ancillary services (Tadesse, 2006). Regional Banks, in contrast, strongly commit to the local development in their scope of business. They cater the financial need of SMEs within their geographic regions. Regional Banks II are the smallest with a more prefectural focus.

To define outputs and input prices, we follow the widely accepted intermediation approach (Sealey and Lindley, 1977). In our cost function, in line with Fukuyama and Weber (2009), Barros et al. (2012), Assaf et al. (2011), we specify two outputs:  $y_1$  net loans and bills discounted, and  $y_2$  earning assets which include investments, securities, and other earning assets. Because of data constraints, we are unable to extract data for personnel expenses or to obtain their share from noninterest expenses. Therefore, we define two input prices: price of fund, and price of physical capital and labour, in line with Fu et al. (2014). Price of fund  $w_1$  is the ratio of interest expenses divided by total deposits and borrowed funds. Price of physical capital and labour  $w_2$  is the ratio of noninterest expenses divided by fixed assets. Equity is included in the cost function as a quasi-fixed input (Hughes and Mester, 2013). Table 1 describes the summary statistics of key variables in our panel data.

[INSERT TABLE 1 ABOUT HERE]

## 5. Empirical results

### 5.1. Cost elasticities with respect to uncontrollable inputs and equity

Estimated parameters satisfy the monotonic condition and linear homogeneity constraints of the cost function.<sup>6</sup> The coefficients are statistically significant with appropriate signs as expected. Bankrupt loans are found to have a slightly stronger impact on cost than restructured loans (the parameters are 0.0384 and 0.0203, respectively). The impact of equity on cost is positive and significant (0.0533). We report the elasticities of cost with respect to bankrupt loans, restructured loans, and equity in Table 2. Overall, for all banks in the sample, these variables expose a cost-augmenting effect. The average cost elasticities with respect to bankrupt loans, restructured loans, and equity are reported at 0.0385, 0.0201, and 0.0537 respectively. In sub-periods, while the cost elasticity with respect to bankrupt loans appears to vary over time, the cost elasticity with respect to restructured loans decrease monotonically, turning out negative in the last two sub-periods (-0.0002 and -0.0106). This negative cost elasticity is attributed to the negative values found for City Banks and Regional Banks I. In terms of equity, there is variability in cost elasticities. The largest magnitude for cost elasticities with respect to equity is in the first two sub-periods, 0.0721 in September 2000-March 2003 and 0.0998 in September 2003-March 2006. This could reflect the high cost of equity prevailing during the acute phase of the banking crisis and the restructuring period. Afterwards, the cost elasticity with respect to equity declines to 0.0415 in September 2006-March 2009, and thereafter, further down to 0.0194 in September 2009-March 2012. This finding is in line with King (2009). King (2009) reports that the magnitude of the cost of equity incurred by Japanese banks is higher compared to that in other countries such as Canada, France, Germany, UK, and US.

---

[INSERT TABLE 2 ABOUT HERE]

Breaking up the cost elasticities according to bank types, we observe a decreasing trend of the cost elasticities with respect to uncontrollable inputs for City Banks. Note that these values are negative in the case of restructured loans in all sub-periods and in the case of bankrupt loans during the September 2012-March 2015 period. For Regional Banks I and II, there is also a downward trend for the cost elasticities with respect to restructured loans. In the September 2009-March 2012 period and September 2012-March 2015 period, there are negative cost elasticities with respect to restructured loans in Regional Banks I. These findings show that restructured loans do not always raise cost. This is an interesting finding, revealing that restructuring the industry through legislation change referring to restructured loans benefits the industry. A component of our restructured loan data relates to loans of which interest rates have been lowered, contracts have been amended, and/or loans to corporations under ongoing reorganisation (Montgomery and Shimizutani, 2009). Without this process, these loans would be more likely to become nonperforming loans, raising further bank costs. Furthermore, to deal with restructured loans, banks have received government support through the Act on Special Measures for Strengthening Financial Functions (August 2004-March 2008). Under this Act, capital injections ensure that financial institutions overcome difficulties in funding so that “*the financial sector can voluntarily commit to risk taking and function as financial intermediaries in the regional economy*” (Endo, 2013). In the aftermath of the collapse of Lehman Brothers, this Act was reactivated in December 2008. From March 1999 to March 2009, there were four capital injection programs, involving 37 financial institutions (Hoshi and Kashyap, 2010). Banks rescued by public capital were then required to increase lending to SMEs. In the Policy Statement on 12/03/2009, Kaoru Yosano (Minister of Finance and Minister of State for Financial Services and Economic and Fiscal Policy) announced that various measures had been enforced to allow financial institutions to supply funds with confidence, “*including prompt*

*enforcement of the amended Act on Special Measures for Strengthening Financial Functions, partially relaxing the capital adequacy requirements of banks, and expanding the scope of cases in which restructured loans to SMEs are not classified as nonperforming loans”.*<sup>7</sup>

Besides, in the basis of the SME Financing Facilitation Act (2008-2013), there were changes in the regulatory framework which allowed bad loans of SMEs to be reclassified. These legislation amendments appear to be effective, as shown in our findings of negative cost elasticities with respect to restructured loans.

Apart from government support measures, the nature of business might also explain for the cost-saving impact of restructured loans. Regional Banks are committed to the development of the local regions where their headquarters are situated. SMEs are among their target clients. Therefore, Regional Banks are motivated to support SMEs through amending bad loans. As a result, 3-6% total credit was reclassified under the SME Financing Facilitation Act (International Monetary Fund, 2012).<sup>8</sup>

---

<sup>7</sup> <http://www.fsa.go.jp/en/announce/state/20090312.html>

<sup>8</sup> City Banks were strongly engaged in a so-called *main bank* system (Hoshino, 2002), in which they had strong ties with their clients. After the second half of the 20<sup>th</sup> century, this business network has gradually shrunk (Lincoln and Shimotani, 2010). In this type of relationship, there exist interlocking shareholdings among banks and their client firms. Apart from funding, banks provide member firms with management assistance. If restructured loans were disposed, banks would terminate their financial relation with the firms in question, and force them to declare bankruptcy. Hence, City Banks might have incentives to carry on funding troubled firms to assist them in regaining their financial health. In addition, as City Banks are the largest commercial bank group, they may have available resources to withstand restructured loans and recover these loans within the time frame set out in the regulatory framework. Furthermore, since October 2012, the Bank of Japan has pursued aggressive quantitative easing and committed to provide unlimited funding to match the net increase in loans to households and non-financial sectors (Bank of Japan’s announcement on 30/10/2012). Although this *Stimulating Bank Lending Facility* benefits financial institutions in terms of funding, this may discourage proper credit screening. These countervailing effects

Another noteworthy finding is the cost-saving impact of equity for City Banks, on average at -0.0221. While the cost elasticity with respect to equity remains positive in all sub-periods for Regional Banks I and II, it is positive only in September 2003 to March 2006 for City Banks. Hence, equity financing might benefit City Banks in terms of mitigating the interest burden from debt financing, supporting the argument of Hughes and Mester (2013). These negative elasticities could also be interpreted as how much banks are willing to pay for equity as it would result in cost saving (Boucinha et al., 2013). Boucinha et al. (2013) also report a desirable impact of equity in lessening costs for Portuguese banks during 1992-2006. In contrast, this may not apply for Regional Banks. Their cost elasticities with respect to equity appear to have variability over time, with a more pronounced magnitude in Regional Banks I (0.0608) than in Regional Banks II (0.0541).

## *5.2. Total factor productivity growth over time*

In Table 3, we report the average values (semi-annually) of TFP growth over time. On average, the productivity growth of Japanese banks during the years 2000-2014 is at 1.52%. In the first sub-period March 2001-March 2003, Japanese banks experienced negative productivity growth, which could be expected since they were undergoing major reforms to restore financial stability post-crisis. In the second sub-period September 2003-March 2006, TFP exhibited a strong growth at an average of 3.53%, thanks to the decline in bankrupt loans and restructured loans. This could also be attributed to the effect of quantitative easing in

---

might be reflected in the negative cost elasticities with respect to bankrupt loans from September 2012 to March 2015. Note that the Japanese economy has been struggling to strive from deflation since 2009, notably indicated by the implementation of negative interest rate in January 2016. If the economic slump is not attributed to banks not willing to lend (due to the fear of bad loans), but the lack of borrowers, there could be less incentive for banks to accelerate the disposal of bankrupt loans.

stimulating economic activity (Girardin and Moussa, 2011).<sup>9</sup> In the third sub-period September 2006-March 2009, TFP growth dropped markedly to 0.17%, possibly because of the onset of the global financial crisis 2007-2008. The destructive effect of the crisis seems short-lived, as TFP growth bounced back and peaked at 3.64% during the September 2009-March 2012 period, followed by a decrease to 2.29% in the last sub-period September 2012-March 2015. Referring to the Japanese banking literature, there are a few studies which estimate bank productivity growth, though not very recent. Using the indirect Malmquist–Russell productivity index, Fukuyama and Weber (2002) report a 2% decline per year on average for Japanese banks operating between 1992 and 1996. Studying Japanese credit cooperative banks and using the bootstrapped Malmquist index, Assaf et al. (2011) find that their productivity growth did not rise significantly during 2000-2006.

[INSERT TABLE 3 ABOUT HERE]

Among bank categories, City Banks were the most productive, on average at 3.28%, followed by Regional Banks I (1.82%). The smallest banks in size, Regional Banks II, performed the lowest growth of 0.87% on average. Fukuyama (1995) also reports that between 1989 and 1991, City Banks were more productive than Regional Banks. In a similar vein, Barros et al. (2012) find that City Banks were the most efficient among the three types during 2000-2007. During the restructuring and the first quantitative easing period (March 2001-March 2006), City Banks experienced substantial growth in their productivity, notably at 9.65% during March 2001-March 2003 and 4.72% during September 2003-March 2006. The other two types, in contrast, underwent negative productivity growth in the restructuring period, -1.67% for Regional Banks I and -4.64% for Regional Banks II. Like City Banks, their productivity growth increased significantly during the initial quantitative easing period

---

<sup>9</sup> Japanese annual GDP growth rate in 2004 was 2.4%, highest since 2000 (source: OECD statistics).

September 2003-March 2006 (3.75% and 3.08%). In the third sub-period September 2006-March 2009, which covers the duration of the global financial crisis 2007-2008, City Banks and Regional Banks I bore a loss in productivity growth. The decline was more prominent in City Banks, -0.63%. On the contrary, Regional Banks II appeared to survive the crisis, though their growth dropped to 0.798%. Afterwards, productivity growth rose to 4.06% in City Banks, 3.87% in Regional Banks I, and 3.24% in Regional Banks II. The last sub-period September 2012-March 2015, which embraces the aggressive quantitative easing, witnessed a considerable decline in productivity growth of City Banks (down to -1.62%). Other bank types also saw a fall in their productivity growth.

### *5.3. Total factor productivity growth decomposition*

To shed more light into the contribution of each component to TFP growth, we report the average values of the effect of each component in Table 4, according to equation (14) of our model. From March 2001 to March 2003, bankrupt loans dampened TFP growth by -0.45. Nevertheless, their negative effect was smaller compared to the impact of restructured loans, -0.49, and the impact of returns to scale, -2.17. Equity and technological change positively contributed to productivity growth by 0.11 and 0.65 respectively. In the second sub-period September 2003-March 2006, large productivity growth was a result of the decline in bankrupt and restructured loans, the rise in the scale effect, and technological progress.

[INSERT TABLE 4 ABOUT HERE]

In the third sub-period September 2006-March 2009, on average, bankrupt loans constrained productivity growth with a magnitude of -0.06. In contrast, from September 2009 onwards, they in fact contributed to productivity gain because there was a drop in the level of bankrupt loans for the whole banking system (gradually down from 8458 billion JPN in September 2009 to 5896 billion JPN in March 2015). Using nonperforming loan ratio as a

control variable in the cost function, Altunbas et al. (2000) find a positive relationship between nonperforming loans and inefficiency. Mamatzakis et al. (2015) also report a negative impact of problem loans on Japanese bank performance. Like bankrupt loans, restructured loans had imposed a negative effect on TFP growth (-0.49) before the implementation of the Takenaka plan. From September 2003 to March 2006, the effectiveness of the rehabilitation program was revealed by the fall in restructured loans, consequently contributing to productivity growth by 0.39%. From September 2006 to March 2015, the positive impact of restructured loans on TFP growth remained. Note that there was an increase in restructured loans in the last two sub-periods. It could be the case that the US credit crunch imposed a destructive effect on Japanese bank productivity growth with a lag, which was reflected in the rise of restructured loans after the crisis. The Tohoku-Pacific Ocean earthquake in March 2011, which has been the most powerful earthquake ever in Japan, might also be among the reasons for the rising of restructured loans afterwards.

Equity was among the growth drivers, although its average impact on productivity growth was small (0.003) for the whole sample period. In the initial sub-period March 2001-March 2003, 0.11% was the contribution of equity to TFP growth. This could stem from the fact that banks were undercapitalised post-crisis, and during that time of uncertainty, the cost of equity financing was high. Nevertheless, banks that failed to raise enough equity were eventually rescued by public capital (Montgomery and Shimizutani, 2009). Therefore, they benefited from government subsidisation and could make use of the bailout capital. In the second and the last sub-periods, equity put more weight on the cost burden, thus eroding productivity growth, -0.23 during September 2003-March 2006 and -0.06 during September 2012-March 2015. Between September 2006 and March 2012, equity positively contributed to productivity growth.

Overall, technical progress was consistently the driving force of TFP growth. Over the whole period, technology accounted for the increase in TFP growth on average at 0.41. Tadesse (2006) also reports evidence for technological progress in Japanese banks between 1974 and 1991. The scale effect, although fluctuating over time, on average was the major contributor to productivity growth (1.08). Boucinha et al. (2013) also find a significant contribution of returns to scale to increased productivity growth of Portuguese banks. Feng and Serletis (2010) find a moderate positive effect of returns to scale on productivity growth of large US banks, on average about 0.44%. Yet, the scale effect is the second largest component (after technical change) of US banks' productivity growth. Computing technical and scale efficiency for Japanese commercial banks in 1990, Fukuyama (1993) reports that scale inefficiency is negligible compared to pure technical inefficiency. Regarding the quasi-fixed input, the magnitude of the contribution of equity over time is not considerable, 0.003. In terms of uncontrollable inputs, bankrupt loans, on average, showed a detrimental impact on TFP growth, -0.07. Restructured loans, in contrast, was among the main driving forces for productivity growth, 0.104. There is evidence to support that the increase in TFP growth during September 2003-March 2006 was partly attributed to the fall in bankrupt loans and restructured loans. The reverse is true for the initial sub-period, when the loss in TFP growth was also mainly explained by the scale effect.

#### *5.4. Total factor productivity decomposition per type of banks*

Table 5 reports the decomposition of TFP growth for each bank type. In terms of the effects of uncontrollable inputs, on average bankrupt loans exhibit a destructive effect on productivity growth of all banks. The magnitude of the impact is greater for City Banks, -0.23, than for Regional Banks I, -0.04, and Regional Banks II, -0.09. In the first sub-period March 2001-March 2003, except City Banks, Regional Banks suffered a damaging effect of bankrupt loans on TFP growth. This finding could indicate that the restructuring scheme had helped City

Banks to cut their bankrupt loan level. Afterwards, Regional Banks had to bear that impairment again during September 2006-March 2009. From September 2003-March 2015, City Banks endured a negative impact of bankrupt loans on productivity growth. It could be that the global financial crisis worsened the likelihood of recovery of bankrupt loans and downgraded restructured loans to bankrupt loans. The effect could be more pronounced in City Banks than in the others because of their size and business structure. Regional Banks are more geographical focus, thus, were less exposed to the contagion effect of the US credit crunch.

[INSERT TABLE 5 ABOUT HERE]

Restructured loans appear beneficial to productivity growth of each bank type. On average, they contributed to TFP growth of all types, more considerably for City Banks, 0.33. Yet, City Banks had to face a negative effect of restructured loans from September 2003 to March 2009. In the initial sub-period, Regional Banks suffered from an adverse effect of restructured loans on their productivity growth, while the contrary is reported for City Banks. In the remaining sub-periods, restructured loans enhanced TFP growth of Regional Banks. In terms of equity, on average, equity undermined productivity growth of Regional Banks II by -0.05, while the effect is favourable for City Banks, 0.21, and Regional Banks I, 0.02. Over time, there was a volatile impact of equity on productivity growth of Regional Banks I. From September 2003 to March 2015, the impact of equity was persistently negative for Regional Banks II, but positive for City Banks.

Regarding the scale effect, the influence of the global financial crisis on all banks could be reflected in our results. The reason is that the contribution of returns to scale declined considerably in the third sub-period, which covers the crisis. It was even negative in City Banks, -0.197 and Regional Banks I, -1.07. This might be due to quantitative easing policy, especially for Regional Banks, as the scale effect was quite large in the second and the last two

sub-periods. Other studies also find that small Japanese banks, in particular Regional Banks, exhibit increasing returns to scale (Altunbas et al., 2000; Azad et al., 2014; Fukuyama, 1993). Interestingly, there exists decreasing returns to scale for City Banks in the last period, -2.51. Previous research on Japanese banks also reports decreasing returns to scale for City Banks (Altunbas et al., 2000; Azad et al., 2014; Drake and Hall, 2003; Tadesse, 2006).

Turning to the effect of technology, we find strong evidence for technological progress in all bank types. Within City Banks, the impact of technological change on productivity growth was greater than this of other banks, 0.69 compared to 0.48 for Regional Banks I and 0.28 for Regional Banks II. From March 2001 to March 2012, Regional Banks II experienced a downward trend of technological progress, with technological regress, -0.05, reported in the September 2009-March 2012 period. In the last sub-period, technological change contributed to productivity growth of all banks. Evaluating technical efficiency of Japanese credit cooperatives, Glass et al. (2014) also find a presence of technical progress between 1998 and 2009. Technical progress also existed for all banks in the early 1990s, although different productivity measures yield different timing for its presence (Fukuyama, 1996).

## **6. Convergence cluster analysis**

The next stage of our analysis investigates whether there is a tendency of convergence in TFP growth across regions and time. During the course of bank restructuring and promoting economic growth, the Japanese government has enacted a variety of support measures, including quantitative easing policy, aiming to raise bank lending to nonfinancial sectors. Hence, if indeed the restructuring were working, we would expect a tendency of convergence in bank productivity growth among banks and across regions over time. We adopt the methodology developed by Phillips and Sul (2007) to identify the integration process in

Japanese banks.<sup>10</sup> In the context of our data, we explore the process of banking integration in the convergence of TFP growth, and the effect of each component in 121 Japanese commercial banks.<sup>11</sup> Matousek et al. (2015) also apply this methodology for testing banking integration in the ‘old’ European Union using bank-level efficiency data. Rughoo and Sarantis (2012) use this approach to test the convergence of deposit and lending rates in the European retail banking market. To our knowledge, our paper would be the first to test for convergence in TFP growth and its components using Phillips and Sul (2007) methodology. The task is to find the speed of convergence *b-hat*, and then apply a one-sided *t*-test. If *t*-statistics  $< -1.65$ , the null hypothesis of convergence is rejected at the 5% level. We report the speed of convergence and associated *t*-statistics in Tables 6 to 9.

### 6.1. Results for bank types

---

<sup>10</sup> Appendix A provides an overview of this methodology. In banking research, two widely used methods to examine convergence are  $\beta$ -convergence and  $\sigma$ -convergence, proposed by Barro et al. (1991) for the growth literature. Banking applications include Andrieş and Căpraru (2014), Casu and Girardone (2010), Fung (2006), Weill (2009) and Weill (2013). If  $\beta$ -convergence regresses the growth rate of any variable on its initial level,  $\sigma$ -convergence measures the cross-sectional dispersion of the level of the variable over time.  $\beta < 0$  implies that there exists a negative correlation between the initial level and the growth rate, which can be expressed as the entity that has a lower starting point has a faster growing speed than their counterparts which have higher initial levels. In the long-run, all observed units would converge to the same steady state. On the other hand, if the dispersion of a cross-section declines over time, there exists  $\sigma$ -convergence which exhibits the speed of each unit’s growth to converge with the average level of the sample.  $\sigma$ -convergence somehow outperforms  $\beta$ -convergence in terms of explanatory power. Quah (1996) indicates a few limitations of  $\beta$ -convergence by referring to a situation where the entity with lower departing point grows so quickly that passes the ones with higher starting points, resulting in no convergence in the long-run.

<sup>11</sup> After computing TFP growth, we exclude some banks from the convergence test because they have too few observations.

We start the analysis by testing for convergence in TFP growth and the effects of the five underlying TFP components over the whole sample. Results from the log  $t$ -test indicate that there is no convergence (see Table 6). Results from the club convergence test also show an absolute absence of convergent clubs. We further repeat the analysis for each bank type. We find no club convergence for Regional Banks II. For the other two types, there exists convergence, reported in Table 6. For Regional Banks I, there is evidence of convergence for this sample in terms of productivity growth ( $b\text{-hat} = -0.122$ ) and its components. However, the speed of convergence is slow as values of  $b\text{-hat}$  are negative in all data series. They are -0.137 for the effect of bankrupt loans, -0.146 for the effect of restructured loans, -0.136 for the effect of equity, -0.059 for the scale effect, and -0.174 for the effect of technological change.

[INSERT TABLE 6 ABOUT HERE]

For the sample of seven City Banks, the tests reveal some convergence clubs. Table 6 also reports the convergence coefficients for City Banks and associated  $t$ -statistics obtained from the log  $t$ -test for six data series. The null hypothesis of convergence in TFP growth in City Banks is rejected at the 5% level ( $b\text{-hat} = -3.458$ ). Similarly, the null hypothesis of convergence for the effect of each component on TFP growth is rejected, which reinforces the divergence of TFP growth.

The next step is to examine if there exists any cluster of convergence in TFP growth as well as in each of its underlying components. We find negative values of  $b\text{-hat}$  associated with almost all convergence clubs. These findings exhibit weak convergence with slow speed as the estimated  $b\text{-hat}$  is insignificantly different from zero. Matousek et al. (2015) also report a few negative  $b\text{-hats}$  in their Phillips and Sul (2007)'s convergence test for technical efficiency of the top 10 EU banks. Regarding TFP growth, we detect one convergence club which is formed of two banks (IDs 1 and 10). The same two banks are reported to constitute the club of

convergence in the effect of bankrupt, restructured loans, equity, and the scale effect. In terms of the impact of technology, there are two clubs of convergence. Banks 1 and 16 are identified in the first club with a faster convergence speed (1.832) than banks 8 and 17 in the second club (-0.928).

## *6.2 Results by geographic regions*

Given that overall there is weak evidence regarding convergence, we further investigate whether there exists any convergence across geographic regions. We classify banks into eight regions based on their headquarters' locations. These eight regions are the eight principal regions of Japan, namely Hokkaido, Tohoku, Kanto, Chubu, Kansai, Chugoku, Shikoku, and Kyushu. Their relative geographic locations are illustrated in the map of Japan in Figure 1. The results are reported in Tables 7 and 8.

[INSERT TABLE 7 ABOUT HERE]

The log  $t$ -test and club convergence test denote that banks in Hokkaido, Tohoku, and Chubu converge in TFP growth. Among these regions, Chubu has the fastest convergence rate, while Tohoku is the slowest. There is no existence of convergence for banks in Kansai and Kyushu (see Table 7). We find some clubs of convergence for banks in Kanto, Chugoku, and Shikoku (see Table 8).

[INSERT TABLE 8 ABOUT HERE]

In our sample, the number of banks in Kanto is the largest compared to the numbers of banks in other regions. There are 24 banks, among which are six City Banks having their headquarters registered in Tokyo, which belongs to Kanto region. Note that City Banks and Regional Banks differ from each other in size, business structure, and focus. Hence, we would expect to find club convergence rather than convergence at the whole sample. In fact, results

indicate a few clubs of convergence in TFP growth and its components. It is noteworthy that the club of banks 5, 16, 129, 522, and the club of banks 133, 135, 138, 526, 597 appear in most of the results for the data tested.

In Chugoku, there is one convergence club, formed of four banks 166, 167, 168, and 169, for productivity growth. The club convergence test for the underlying components of TFP growth also identifies this club. There is an additional convergence club (bank IDs: 170 and 565) with slow convergence rate for the effect of restructured loans ( $b\text{-hat} = -5.27$ ) and equity ( $b\text{-hat} = -5.42$ ). Eight banks in the remaining region, Shikoku, converge in TFP growth ( $b\text{-hat} = 2.256$ ). There also exists convergence in the effect of bankrupt loans ( $b\text{-hat} = -0.959$ ), equity ( $b\text{-hat} = 2.714$ ) and the scale effect ( $b\text{-hat} = 3.902$ ). For the effect of restructured loans and technological change, there are convergence clubs instead. One club of convergence, constituted by banks 173, 174, 175, and 578, is reported for the effect of restructured loans ( $b\text{-hat} = 2.297$ ). For the impact of technological change, only bank 572 is not classified in the club of convergence.

Overall, in eight principal geographic regions of Japan, there are four regions where there exists convergence in terms of productivity growth. We proceed by investigating further whether that convergence behaviour is present between regions. The data are averaged for each region and are applied for between-region convergence.<sup>12</sup> Interestingly, all regions converge in terms of the impacts of bankrupt loans ( $b\text{-hat} = 0.112$ ) and equity ( $b\text{-hat} = 2.931$ ) on TFP growth (see Table 9). There exists clubs of convergence in other components of TFP growth. Regarding restructured loans, Tohoku, Chugoku, and Shikoku belong to one convergence club. With regard to the scale effect, there are two clubs. Club one (Tohoku, Chubu, Chugoku, and Shikoku) experiences a faster convergent process (at the rate of 1.553) compared to club two

---

<sup>12</sup> The graphs of the transition paths for TFP growth and the impact of each component are available upon request.

(Hokkaido and Kanto). Regarding technological change, the tests reveal three clubs of convergence.

[INSERT TABLE 9 ABOUT HERE]

Alas, convergence in TFP growth is not present between regions. The club convergence test uncovers two convergence clubs, which are illustrated in Figure 1 by the green and blue areas. The first club consists of two regions: Tohoku and Shikoku. The second club includes three regions, namely, Kanto, Chubu, and Chugoku. There are 73 Regional Banks and 6 City Banks in these five regions, constituting 65.3% of the number of banks in our sample. The null hypothesis of convergence in productivity growth is rejected for the remaining regions, which are displayed in red areas in Figure 1. This finding lends some support for limited convergence.

[INSERT FIGURE 1 ABOUT HERE]

Note from the map that Kanto and Chubu, two regions classified in convergence club two, are adjacent. This finding may suggest that apart from City Banks, Regional Banks, which have their head offices in one region, may also operate in adjacent regions through their local branch network. This is in line with findings from Kano and Tsutsui (2003) who investigate the geographic segmentation in the loan market of Japanese banks. They provide evidence for an absence of loan market segmentation within Regional Banks as these banks can operate through their branches in adjacent prefectures. Kano and Tsutsui (2003) show that about 18.9% of Regional Banks in their sample had branches outside their head offices' prefectures. Hence, partially overlapping operational areas exist among Regional Banks. Kanto is well known as Japan's economic heart, with Tokyo being one of the most important economic centres. Based on regional economic data in 2012, Kanto's gross regional product and income (1,886,166 and

1,439,151 hundred million JPY) were the highest among eight regions.<sup>13</sup> As previously mentioned, the majority of City Banks have their headquarters registered in Kanto. It could be the impact of their branch network that results in the integration process existing in these regions.

Interestingly, although being classified in the same convergence club, Tohoku and Shikoku are in fact geographically distant from each other. The last divergence club also consists of regions that are scattered across the country. Hokkaido and Kyushu are the two far-ends of Japan surface area, and they are not geographic neighbours with Kansai either. Kansai is another region, beside Kanto, contributing significantly to Japan's economic wealth. It could be due to the significant disparities in economic features that these regions are in the divergence group of productivity growth. The regional-related factors that distinguish banks in these diverging regions would be an interesting issue for future research.

## **7. Conclusion**

This study quantifies the impact of uncontrollable inputs on productivity growth of Japanese commercial banks. We adopt a parametric methodology which allows for a decomposition of TFP growth with respect to the impact of uncontrollable inputs, namely bankrupt and restructured loans. Our finding reports an average productivity growth of 1.52% semi-annually. Productivity growth deteriorated during the restructuring period (2001-2003) and the following global financial crisis. Alongside the downturn of the scale effect, the loss in productivity growth was attributed to the adverse effect of bankrupt loans and the negative impact of equity in a few periods. There exists evidence showing that some legislation changes

---

have benefited the banking industry, indicated by the cost-reducing impact of restructured loans.

We further proceed with convergence tests for TFP growth and its components. The presented results have important policy implications. Over 15 years, there has been heterogeneity among banks, as they are recognised as diverging altogether. Nevertheless, within City Banks, there is some evidence of slow convergence. Regional Banks that operate in the same geographic regions appear to develop with some degree of commonality. The evidence of a banking integration process within and across some regions would assist policymakers to design appropriate schemes to promote growth. As the banking system remains the important channel to convey the economic impact of *Abenomics* – the current economic policy to combat deflation and boost growth, bank productivity growth would act as a signal for the effectiveness of this policy. It would be worth looking into the characteristics of the diverging regions so that modified versions of these policies would be more applicable.

Given the negative interest rate policy enacted in January 2016 for the first time in Japan's history, bank productivity gain could be an important indication for the efficacy of this central banking policy. However, negative interest rates should be accompanied by prudent lending standards and proper supervision in order not to increase the risk of bankrupt and restructured loans. Additionally, potential challenges associated with prolonged negative interest rates may limit bank productivity growth by, for example, lowering outputs. For instance, the fear of substantial deposit withdrawals may inhibit banks to pass the cost of negative rates on to retail depositors. Hence, if banks have to incur this cost, they may be reluctant to increase lending due to low profit margin (Bech and Malkhozov, 2016). These policy limitations are beyond the scope of this paper. It would be an interesting area for future research to observe and study the benefits and drawbacks of negative interest rate on Japanese bank productivity growth.

## Appendix A. Log $t$ -test and club convergence test

The Phillips and Sul (2007) approach is more advanced compared to  $\beta$ -convergence and  $\sigma$ -convergence. It accounts for both common and heterogeneous components of a panel data variable. That systemic idiosyncratic element is also allowed to evolve over time. Furthermore, Phillips and Sul (2007) argue that the rejection of the null hypothesis of convergence does not always mean that there is no convergence among sub-groups of the panel. Their clustering algorithm can unfold the existence of club convergence within the panel. The transition parameter and the regression  $t$  test can be summarised as follows:

The variable of interest  $X_{it}$  (in our study, it is TFP growth and its components) in a context of a panel data can be decomposed into a systemic component  $g_{it}$ , and a transitory component  $a_{it}$ :

$$X_{it} = g_{it} + a_{it} \quad \text{Eq. (A.1)}$$

To distinguish between the common and idiosyncratic components which may be embraced in  $g_{it}$  and  $a_{it}$ , equation (A.1) can be reformulated as:

$$X_{it} = \left( \frac{g_{it} + a_{it}}{\mu_t} \right) \mu_t = \delta_{it} \mu_t \quad \text{Eq. (A.2)}$$

with  $\mu_t$  is a single common component and  $\delta_{it}$  is a time-varying idiosyncratic element measuring the relative share in  $\mu_t$  of individual  $i$  at time  $t$ .

Phillips and Sul (2007) define the relative transition coefficient  $h_{it}$  and obtain  $\delta_{it}$  as follows:

$$h_{it} = \frac{X_{it}}{\frac{1}{N} \sum_{i=1}^N X_{it}} = \frac{\delta_{it} \mu_t}{\frac{1}{N} \sum_{i=1}^N \delta_{it} \mu_t} = \frac{\delta_{it}}{\frac{1}{N} \sum_{i=1}^N \delta_{it}} \quad \text{Eq. (A.3)}$$

The objective is to test whether the factor loading coefficients  $\delta_{it}$  converge to  $\delta$ , which means the relative transition coefficients  $h_{it}$  converge to unity. Hence, in the long run, the cross-sectional variance of  $h_{it}$   $\left( \sigma_t^2 = (1/N) \sum_{i=1}^N (h_{it} - 1)^2 \right)$  converges to zero.

The regression test of convergence is a regression  $t$  test for the null hypothesis of convergence  $H_0: \delta_i = \delta$  and  $\alpha \geq 0$ , where  $\alpha$  is the decay rate<sup>14</sup>, against the alternative hypothesis  $H_a: \delta_i \neq \delta$  for all  $i$  or  $\alpha < 0$ . The log  $t$  regression is conducted in three steps:

i) Calculate the cross-sectional variance ratio  $H_1/H_t$ , where  $H_t = (1/N) \sum_{i=1}^N (\hat{h}_{it} - 1)^2$

ii) Perform the OLS regression:  $\log(H_1/H_t) - 2 \log L(t) = \hat{a} + \hat{b} \log t + \hat{u}_t$  Eq. (A.4)

where the fitted coefficient of  $\log t$ ,  $\hat{b}$ ,  $\hat{b} = 2\hat{\alpha}$ , is the estimate of the speed of convergence, and  $\hat{\alpha}$  is the estimate of  $\alpha$  in  $H_0$ , and  $L(t) = \log(t+1)$ . Phillips and Sul (2007) recommend that the data for this regression start at  $t = rT$ , with  $r = 0.3$  obtained from Phillips and Sul (2007)'s Monte-Carlo regression.

iii) Apply an autocorrelation and heteroskedasticity (HAC) robust one-sided  $t$  test of the inequality null hypothesis  $\alpha \geq 0$  using  $\hat{b}$  and a HAC standard error. If  $t$ -statistics  $< -1.65$ , the null hypothesis of convergence is rejected at the 5% level.<sup>15</sup>

---

<sup>14</sup> Phillips and Sul (2007) show that the formulation for  $\delta_{it}$  ensures it converges to  $\delta_i$  for all  $\alpha \geq 0$ . Refer to their paper for the derivation of the log  $t$  regression equation.

<sup>15</sup> For the procedure to test for club convergence, please refer to Phillips and Sul (2007), pp. 1798-1801 for more details.

Table 1. Descriptive statistics

Variable	Name	Mean	Std.Dev	Min	Max
TC	Total costs	57,055	172,876	153	2,267,130
Y1	Net loans and bills discounted	3,342,342	8,387,483	124,016	76,700,336
Y2	Earning assets	2,205,550	7,692,617	783	78,602,674
w1	Price of fund	0.001233	0.001395	0.00013	0.026086
w2	Price of physical capital and labour	0.757155	0.424054	0.003431	7.55578
BRL	Bankrupt loans	89,107	197,591	2,698	3,522,077
RSL	Restructured loans	43,424	154,252	48	2,701,164
E	Equity	242,010	678,690	2,845	7,425,766

Notes: This Table reports summary statistics of main variables used in the translog cost function. Apart from  $w_1$  and  $w_2$ , all other variables are in Million JPY. Total cost = interest expenses + noninterest expenses. Net loans and bills discounted = loans and bills discounted – bankrupt loans – restructured loans. Earning assets are call loans, receivables under resale agreement, receivables under securities borrowing transactions, bills bought, monetary claims bought, foreign exchanges, customers' liabilities for acceptances and guarantees, investment securities, and other assets. Price of financial capital = interest expenses/(deposits + borrowed funds). Price of overhead = noninterest expense/fixed assets. Bankrupt loans = loans to borrowers in legal bankruptcy + past due loans in arrears by 6 months or more. Restructured loans = past due loans in arrears by 3 months but less than 6 months + restructured loans. Std.Dev: Standard Deviation.

Table 2. The elasticity of cost with respect to uncontrollable inputs and equity.

Notes: This Table reports the effects of bankrupt loans (BRL), restructured loans (RSL), equity, scale, and technological change on TFP growth for all banks. The figures are averaged per 6 semi-annual periods, except the first time frame which includes 5 semi-annual periods. All values are in % and may not sum due to averaging and rounding. The sum of each row equals total factor productivity growth reported in Table 3 for all banks.

Notes: This Table reports the effects of bankrupt loans (BRL), restructured loans (RSL), equity, scale, and technological change on TFP growth for all banks. The figures are averaged per 6 semi-annual periods, except the first time frame which includes 5 semi-annual periods. All values are in % and may not sum due to averaging and rounding. The sum of five components for each bank type in each row equals total factor productivity growth reported in Table 3 per bank type.

Table 6. Log  $t$ -test and club convergence test – All banks and per bank type.

Bank types	Data series	Clubs	Bank IDs	$b$ -hat	$t$ -statistics
All banks	TFP growth	All banks: Divergent		-1.781	-13.193*

Notes: This Table reports the log  $t$ -test and club convergence test for TFP growth and the effect of each component on TFP growth in all banks and each bank type. The Phillips and Sul (2007) log  $t$ -test and club convergence test were run in OxEdit using the Gauss code by Sul (2007).  $b$ -hat is the convergence coefficient or speed of convergence. If  $t$ -statistics < -1.65, the null hypothesis of convergence is rejected at the 5% significance level. The corresponding bank IDs are reported for each convergent club. \* indicates rejection of the null hypothesis of convergence at the 5% significance level.

Table 7. Log  $t$ -test and club convergence test in Hokkaido, Tohoku, Chubu, Kyushu, and Kansai.

Region	Data	$b$ -hat	$t$ -stat	Region	Data	$b$ -hat	$t$ -stat

	RSL	2.184	1.341				
	Equity	1.858	1.285				
	Scale	2.002	1.381				
	Tech.	2.032	1.586				

Notes: This Table reports the log  $t$ -test and club convergence test for TFP growth and the effect of each component on TFP growth per region. The numbers of banks are: 3 in Hokkaido, 16 in Tohoku, 21 in Chubu, 18 in Kansai, and 21 in Kyushu. The data are total factor productivity growth (TFP), the effect of bankrupt loans (BRL), restructured loans (RSL), equity, the scale effect and technological change (Tech.) on TFP growth. The Phillips and Sul (2007) log  $t$ -test and club convergence test were run in OxEdit using the Gauss code by Sul (2007).  $b$ -hat is the convergence coefficient or speed of convergence. If  $t$ -statistics ( $t$ -stat) $<-1.65$ , the null hypothesis of convergence is rejected at the 5% significance level. If the null is rejected, we conduct club convergence test. \* indicates rejection of the null hypothesis of convergence at the 5% significance level.

Table 8. Log  $t$ -test and club convergence test in Kanto, Chugoku, and Shikoku.

Notes: This Table reports the log  $t$ -test and club convergence test for TFP growth and the effect of each component on TFP growth per region. The numbers of banks are: 24 in Kanto, 10 in Chugoku, and 8 in Shikoku. The data are total factor productivity growth (TFP), the effect of bankrupt loans (BRL), restructured loans (RSL), equity, the scale effect and technological change (Tech.) on TFP growth. The Phillips and Sul (2007) log  $t$ -test and club convergence test were run in OxEdit using the Gauss code by Sul (2007).  $b$ -hat is the convergence coefficient or speed of convergence. If  $t$ -statistics ( $t$ -stat) $<-1.65$ , the null hypothesis of convergence is rejected at the 5% significance level. If the null is rejected, we conduct club convergence test. The corresponding bank IDs are reported for each convergent club. \* indicates rejection of the null hypothesis of convergence at the 5% significance level.

Table 9. Log  $t$ -test and club convergence test across regions.

Data series	Clubs	$b$ -hat	$t$ -statistics
TFP growth	All regions: Divergent	-2.328	-9.97*
	Club 1: Tohoku, Shikoku	5.634	3.997
	Club 2: Kanto, Chubu, Chugoku	0.789	1.666
	Club 3: Divergent	-8.016	-9.792*
BRL effect	All regions: Convergent	0.112	0.109
RSL effect	All regions: Divergent	-4.554	-9.693*
	Club 1: Tohoku, Chugoku, Shikoku	0.136	0.136
	Club 2: Divergent	-6.592	-13.244*
Equity effect	All regions: Convergent	2.931	1.5
Scale effect	All regions: Divergent	-1.439	-3.861*
	Club 1: Tohoku, Chubu, Chugoku, Shikoku	1.553	7.965
	Club 2: Hokkaido, Kanto	0.936	0.924
	Club 3: Divergent	-7.677	-9.523*
Technological change	All regions: Divergent	-4.147	-57.098*
	Club 1: Hokkaido, Kanto	-0.235	-0.402
	Club 2: Chubu, Chugoku	0.651	4.307
	Club 3: Tohoku, Kyushu	0.107	0.146
	Club 4: Divergent	-4.482	-46.464*

Notes: This Table reports the log  $t$ -test and club convergence test for regional average TFP growth and the effect of each component on TFP growth of banks across regions. The data are total factor productivity growth (TFP), the effect of bankrupt loans (BRL), restructured loans (RSL), equity, the scale effect and technological change on TFP growth. The Phillips and Sul (2007) log  $t$ -test and club convergence test were run in OxEdit using the Gauss code by Sul (2007).  $b$ -hat is the convergence coefficient or speed of convergence. If  $t$ -statistics < -1.65, the null hypothesis of convergence is rejected at the 5% significance level. If the null is rejected, we conduct club convergence test. The corresponding regions are reported for each convergent club. \* indicates rejection of the null hypothesis of convergence at the 5% significance level.

Figure 1. Convergence in total factor productivity growth – Japan map.

Notes: This map illustrates the convergence in total factor productivity growth across regions.
